Preface to Developmental Psychopathology, Second Edition

It has been over a decade since the first two volumes of *Developmental Psychopathology* were published. These volumes were extremely well received: They have been highly cited in the literature and they have served as a valuable resource for researchers and practitioners alike. The expansion of the second edition of *Developmental Psychopathology* from two to three volumes speaks to the continued growth of the field, as well as to the ascendance of theory and research in the area of neuroscience informed by a developmental perspective.

There can be no doubt that the discipline of developmental psychopathology has grown significantly in a relatively short period of time. The more than 30 years that have elapsed since the initiation of the schizophrenia high-risk projects (Garmezy & Streitan, 1974) have been marked by significant contributions to the field. Noteworthy among these are the publication of Achenbach's (1974) first text, Rutter and Garmezy's (1983) chapter in the *Handbook of Child Psychology*, and the continued growth of the journal *Development and Psychopathology*, including the Millennium Special Issue entitled *Reflecting on the Past and Planning for the Future of Developmental Psychopathology* (Cicchetti & Sroufe, 2000). A not insignificant contributor to this rapid growth can be found in the very definitional parameters of the discipline. Theorists and researchers in the field of developmental psychopathology use a lifespan framework to elucidate the many factors that can contribute to the development of mental disorders in individuals at high risk, as well as those operative in individuals who have already manifested psychological disturbances or who have averted such disorders despite their high risk status. In essence, a developmental psychopathology perspective provides a broad, integrative framework within which the contributions of diverse disciplines can be incorporated and enhanced (Cicchetti & Sroufe, 2000). Thus, rather than having to develop new theories and methods, those

working within a developmental psychopathology framework can build on and extend previously established traditions. The ability to incorporate knowledge from diverse disciplines and to encourage interdisciplinary research will expedite growth within the field of developmental psychopathology.

As with the previous edition, the current volumes were not organized exclusively around thematic psychiatric disorders. Rather, authors were encouraged to explore developmentally relevant theories, methods of assessment, and domains of functioning. Although many chapters do address specific psychiatric disorders, it is the processes that contribute to the emergence of psychopathology that are emphasized rather than the psychiatric disorders per se.

Volume I, *Theory and Method* presents various approaches to understanding developmental influences on risk and maladaptation. As previously, the volume begins with an explication of the discipline of developmental psychopathology. Within this chapter, a number of significant advances within the field are noted, including the increased attention to processes and mechanisms, the use of multiple levels of analysis, the rise of developmental neuroscience, and the evolution of translational research paradigms. Chapters address a range of topics, including approaches to diagnoses of disorders, developmental epidemiology, diverse theoretical perspectives, various contextual issues, and new frontiers in statistical techniques for developmental phenomena. The volume concludes with a chapter on prevention and intervention.

Volume II, *Developmental Neuroscience*, was added to acknowledge the significant growth in this area since the publication of the first edition of this *Handbook*. Given the seminal historical role that neuroscience played in the emergence of developmental psychopathology (Cicchetti, 1990; Cicchetti & Posner, 2005), it is only fitting that developmental neuroscience has both informed and been informed by developmental psychopathology theorizing.

Neural plasticity, brain imaging, behavioral and molecular genetics, stress and neurobiology, immunology, and environmental influences on brain development are covered in this volume.

Volume III, *Risk, Disorder, and Adaptation* presents various perspectives on contributors to disorder. For example, chapters address the role of social support, family processes, and early experience on adaptation and maladaptation. Other chapters address specific disorders, including mental retardation, language disorders, autism, disorders of attention, obsessive-compulsive disorders, Tourette's syndrome, social anxiety, schizophrenia, anti-social disorders, substance abuse, and dissociative disorders. A number of chapters on resilience despite adversity also are included. The volume concludes with a chapter on stigma and mental illness.

All authors were asked to conclude their chapters with discussions of future research directions and needs. Thus, these volumes serve not only to highlight current knowledge in the field of developmental psychopathology, but also to suggest avenues to pursue for progress to continue. In particular, it is increasingly important to incorporate multiple-levels-of-analysis approaches when investigating maladaptation, psychopathology, and resilience (Cicchetti & Blender, 2004; Cicchetti & Dawson, 2002). The examination of multiple systems, domains, and ecological levels in the same individuals over developmental time will yield a more complete depiction of individual patterns of adaptation and maladaptation. Moreover, such methods are likely to be extremely valuable in elucidating how interventions may affect brain-behavior relations (see, e.g., Caspi et al., 2002, 2003; Cicchetti & Posner, 2005; Fishbein, 2000; Goldapple et al., 2004; Kandel, 1979, 1998, 1999). Such endeavors could result in significant progress toward understanding psychopathology, highlighting efficacious interventions, and ultimately decreasing the burden of mental illness (Cicchetti & Toth, in press).

I now turn to more personal considerations. Although Donald Cohen is no longer with us, he worked closely with me as we developed our plans for the second edition of *Developmental Psychopathology*. Given our collaboration on the first edition of the volumes and our discussions leading up to the publication of these volumes, I thought it only fitting that he be listed as my coauthor. I believe in my heart that Donald would be pleased to have his name affiliated with these volumes and when I shared this plan with his wife, Phyllis, she gave her enthusiastic endorsement. However, I hasten to add that, unfortunately, Donald's illness and untimely death precluded his active involvement in editing the chapters in these volumes. Thus, despite our many

conversations as the plan for these volumes unfolded, I alone am responsible for the final editing of all chapters.

In closing, I want to dedicate these volumes to my dear friend, Marianne Gerschel. Marianne is a true visionary and she has contributed significantly to my work in the area of developmental psychopathology. Without her belief in the value of this field, my efforts and accomplishments would have been greatly compromised.

Finally, as I write this preface, I am ending a significant era in my life. After more than two decades as the director of Mt. Hope Family Center, I am leaving Rochester and to accept a position at the Institute of Child Development, University of Minnesota. There I will be the director of an interdisciplinary center that will emphasize a multiple-levels-of-analysis approach to research and intervention in developmental psychopathology.

This transition is difficult, as Mt. Hope Family Center and my colleagues there have contributed greatly to the growth and development of the field of developmental psychopathology. It is reassuring to know that Mt. Hope Family Center will continue to build upon a solid foundation under the capable directorship of my long-time collaborator and friend, Sheree L. Toth. Although I welcome the new opportunities and challenges that await me, I cannot help being a bit sad to leave. My spirits are buoyed by the knowledge that my work at Mt. Hope Family Center will continue and by my excitement at returning to my roots at the Institute of Child Development where I will have both University and community support to use the field of developmental psychopathology to extend my vision for helping disenfranchised individuals and families throughout the nation and the world.

In this chapter, we discuss the principles inherent to a developmental psychopathology perspective. We want to underscore that, if taken in isolation, many aspects of a developmental approach to psychopathology can be found in other fields that focus on the study of individuals with high-risk conditions and mental disorders. Nonetheless, the incorporation and integration of previously discrete concepts serve to set developmental psychopathology apart from other disciplines. In particular, a focus on the interplay between normality and pathology, the growing acceptance of the importance of a multiple-levels-of-analysis and multidomain approach, and an emphasis on the utilization of a developmental framework for comprehending adaptation and maladaptation across the life course are among those elements that are central to a developmental psychopathology approach. Whereas traditional viewpoints conceptualize maladaptation and disorder as inherent to the individual, the developmental psychopathology framework places them in the dynamic relationship between the individual and the internal and external contexts (Cicchetti, 1987; Sameroff, 2000). Rather than competing with existing theories and facts, the developmental psychopathology perspective provides a broad, integrative framework within which the contributions of separate disciplines can be finally realized in the larger context of understanding individual development and functioning. It is our conviction that the principles of developmental psychopathology

provide a much-needed conceptual scaffolding for facilitating this multidisciplinary integration.

To begin, we describe principles that have guided the field of developmental psychopathology. We then examine the historical origins of the field. We next explicate the definitional parameters of the discipline and discuss issues that are integral to research conducted within a developmental psychopathology framework. We conclude by describing some important future directions for prevention, research on interventions, and research on developmental psychopathology.

WHAT IS DEVELOPMENTAL PSYCHOPATHOLOGY?

Developmental psychopathology is an evolving scientific discipline whose predominant focus is elucidating the interplay among the biological, psychological, and social-contextual aspects of normal and abnormal development across the life span (Cicchetti, 1993; Cicchetti & Toth, 1998; Rutter & Sroufe, 2000; Sameroff, 2000). In their seminal article, Sroufe and Rutter (1984, p. 18) proposed that developmental psychopathology could be defined as “the study of the origins and course of individual patterns of behavioral maladaptation, whatever the age of onset, whatever the causes, whatever the transformations in behavioral

2 Development and Psychopathology

manifestation, and however complex the course of the developmental pattern may be.” Relatedly, the Institute of Medicine (1989) produced a report, entitled *Research on Children and Adolescents with Mental, Behavioral, and Developmental Disorders*, written from the integrative perspective of developmental psychopathology and highly influential in the development of the *National Plan for Research on Child and Adolescent Mental Disorders* (National Advisory Mental Health Council, 1990; see also Jensen et al., 1993). In its report, the Institute stated that a developmental psychopathology approach should take into account “the emerging behavioral repertoire, cognitive and language functions, social and emotional processes, and changes occurring in anatomical structures and physiological processes of the brain” (p. 14).

Given the intimate relation between the study of normality and psychopathology, theoreticians and researchers who predominantly focus on normal processes also espouse similar perspectives about the nature of development. For example, Cairns (1990, p. 42) conceptualized the study of normal development as necessitating a holistic, synthetic science: “Maturational, experiential, and cultural contributions are inseparably coalesced in ontogeny. Hence, developmental studies should be multilevel, concerned with ontogenetic integration, and employ person-oriented as well as variable-oriented analyses.”

In a related vein, Gottlieb (1991, p. 7; see also Gottlieb, Wahlsten, & Lickliter, 1998) depicted individual normal development as characterized by

an increase of complexity of organization (i.e., the emergence of new structural and functional properties and competencies) at all levels of analysis (e.g., molecular, subcellular, cellular, organismic) as a consequence of horizontal and vertical coactions among the organisms’ parts, including organism-environment coactions.

For Gottlieb (1992), horizontal coactions take place at the same level of analysis (e.g., gene-gene, cell-cell, person-person, environment-environment), whereas vertical coactions occur at a different level of analysis (e.g., cell-tissue, organism-environment, behavioral activity-nervous system) and are reciprocal. As such, vertical coactions are capable of influencing developmental organization from either lower-to-higher or higher-to-lower levels of the developing system (Gottlieb, 1992). Thus, epigenesis is viewed as probabilistic rather than predetermined, with the bidirectional nature of genetic, neural, behavioral, and environmental influence over the course of individual development capturing the essence of Gottlieb’s conception of probabilistic

epigenesis. In an earlier period, the influential psychiatrist Adolf Meyer proffered a psychobiological orientation to normality and psychopathology that bore striking similarity to Gottlieb’s more contemporary position. For Meyer (1950, 1957; see also Rutter, 1988), the psychobiological approach depicted humans as integrated organisms such that their thoughts and emotions could affect their functioning all the way down to the cellular and biochemical level, and conversely, that occurrences at these lower biological levels could influence thinking and feeling.

In one of the initial statements concerning the goals of developmental psychopathology, Cicchetti (1990, p. 20) remarked, “Developmental psychopathology should bridge fields of study, span the life cycle, and aid in the discovery of important new truths about the processes underlying adaptation and maladaptation, as well as the best means of preventing or ameliorating psychopathology.” Cicchetti further commented, “This discipline should contribute greatly to reducing the dualisms that exist between the clinical study of and research into childhood and adult disorders, between the behavioral and biological sciences, between developmental psychology and psychopathology, and between basic and applied science” (p. 20).

Theorists and researchers in the field of developmental psychopathology aim to bring together, within a life span framework, the many contributions to the study of individuals at high risk for developing mental disorders and those who have already manifested such disorders. Developmental psychopathologists do not espouse or adhere to a particular theory that could account for all developmental phenomena (Cicchetti & Sroufe, 2000; Rutter & Sroufe, 2000). Rather, they seek to integrate knowledge across scientific disciplines at multiple levels of analysis and within and between developmental domains (Cicchetti & Blender, 2004; Cicchetti & Dawson, 2002; Cicchetti & Posner, in press; see also Cacioppo, Bernston, Sheridan, & McClintock, 2000, and Kosslyn et al., 2002).

Developmental psychopathologists strive to engage in a comprehensive evaluation of biological, psychological, social, and cultural processes and to ascertain how the interaction among these multiple levels of analysis may influence individual differences, the continuity or discontinuity of adaptive or maladaptive behavioral patterns, and the pathways by which normal and pathological developmental outcomes may be achieved (Cicchetti & Dawson, 2002; Cicchetti & Sroufe, 2000). In practice, this entails comprehension of and appreciation for the developmental transformations and reorganizations that occur over time; an analysis of the risk and protective factors and mechanisms operating within and outside the individual and his

or her environment over the course of development; the investigation of how emergent functions, competencies, and developmental tasks modify the expression of a disorder or lead to new symptoms and difficulties; and the recognition that a particular stressor or set of stressful circumstances may eventuate in different biological and psychological difficulties, depending on when in the developmental period the stress occurs (Cicchetti & Aber, 1986; Cicchetti & Cannon, 1999; Cicchetti & Walker, 2001, 2003; Gunnar, Morison, Chisholm, & Shchuder, 2001; Institute of Medicine, 1989; Rutter, 1988; Sanchez, Ladd, & Plotsky, 2001). Moreover, various difficulties will constitute different meanings for an individual depending on cultural considerations (Garcia Coll, Akerman, & Cicchetti, 2000), as well as an individual's experiential history and current level of psychological and biological organization and functioning. The integration of the experience, in turn, will affect the adaptation or maladaptation that ensues.

Developmental psychopathologists stress that disordered individuals may move between pathological and nonpathological forms of functioning. In addition, even in the midst of psychopathology, individuals may display adaptive and maladaptive processes so that it becomes possible to delimit the presence, nature, and boundaries of the underlying psychopathology. Furthermore, developmental psychopathology is a perspective that is especially applicable to the investigation of transitional points in development across the life span (Rutter, 1990; Schulenberg, Sameroff, & Cicchetti, 2004). Development extends throughout the entire course of life, and adaptive and maladaptive processes emerge over the life span. From infancy through senescence, each period of life has its own developmental agenda and contributes in a unique manner to the past, present, and future organization of individual development. Rutter has conjectured that key life turning points may be times when the presence of protective mechanisms could help individuals redirect themselves from a risk trajectory onto a more adaptive developmental pathway (Elder, 1974; Quinton & Rutter, 1988). Likewise, Toth and Cicchetti (1999) have suggested that these periods of developmental transition may also be times when individuals are most amenable to profiting from therapeutic interventions.

With respect to the emergence of psychopathology, all periods of life are consequential in that the developmental process may undergo a pernicious turn toward mental disorder at any phase (Cicchetti & Cannon, 1999; Cicchetti & Walker, 2003; Moffitt, 1993; Post, Weiss, & Leverich, 1994; Rutter, 1996; Zigler & Glick, 1986). Many mental disorders have several distinct phases (Rutter & Sroufe, 2000). The factors that are associated with the onset of a

disorder may be very different from those that are associated with the cessation of a disorder or with its repeated occurrence (Courchesne, Townsend, & Chase, 1995; Post et al., 1996). In contrast to the often dichotomous world of mental disorder/nondisorder depicted in psychiatry, a developmental psychopathology perspective recognizes that normality often fades into abnormality, that adaptive and maladaptive may take on differing definitions depending on whether one's time referent is immediate circumstances or long-term development, and that processes within the individual can be characterized as having shades or degrees of psychopathology.

Since the field of developmental psychopathology has emerged as a new science that is the product of an integration of various disciplines, the efforts of which had been previously distinct and separate (Cicchetti, 1984b, 1990), it has contributed to dramatic knowledge gains in the multiple biological and psychological domains of child and adult development (Cicchetti & Cohen, 1995a, 1995b; Cicchetti & Sroufe, 2000; Rutter & Sroufe, 2000). Notably, there has been an emphasis on increasingly specific process-level models of normal and abnormal development, an acknowledgment that multiple pathways exist to the same outcome and that the effects of one component's value may vary in different systems, and an intensification of interest in biological and genetic factors, as well as in social and contextual factors related to the development of maladaptation and psychopathology (Caspi et al., 2002, 2003; Cicchetti & Aber, 1998; Cicchetti & Cannon, 1999; Cicchetti & Posner, *in press*; Cicchetti & Rogosch, 1996; Cicchetti & Tucker, 1994; Cummings, Davies, & Campbell, 2000; Gottesman & Hanson, 2005; Plomin & McGuffin, 2003; Plomin & Rutter, 1998; Rutter et al., 1997; Sameroff, 2000).

Although process-oriented research continues to be underrepresented in the field, there are a number of notable exceptions. Moreover, there is increasing recognition of the dynamic interplay of influences over developmental time. Perhaps the most dramatic example of this is the work on experience-dependent brain development (Black, Jones, Nelson, & Greenough, 1998; Greenough, Black, & Wallace, 1987). The viewpoint is now widely shared that neurobiological development and experience are mutually influencing (Cicchetti & Tucker, 1994; Eisenberg, 1995; Nelson & Bloom, 1997). Brain development impacts behavior, of course; however, the development of the brain itself is impacted by experience. Specifically, it has been demonstrated that social and psychological experiences can modify gene expression and brain structure, functioning, and organization. Alterations in gene expression influenced by social and psychological experiences produce

4 Development and Psychopathology

changes in patterns of neuronal and synaptic connections (E. R. Kandel, 1998, 1999). These changes not only contribute to the biological bases of individuality, but also play a prominent role in initiating and maintaining the behavioral anomalies that are induced by social and psychological experiences.

Although not in the vocabulary of psychopathologists until the past several decades, concepts of pathways to psychopathology are now prominent in the field (Cicchetti, 1990; Cicchetti & Rogosch, 1996; Sroufe, 1989), having been in use in biology (Mayr, 1964; von Bertalanffy, 1968). It is now common knowledge that subgroups of individuals manifesting similar problems arrived at them from different beginnings (known as equifinality) and that the same risk factors may be associated with different outcomes (known as multifinality). This understanding has proven to be critical, not only because it has the potential to bring about important refinements in the diagnostic classification of mental disorders, but also because it calls attention to the importance of continuing to conduct process-oriented investigations (cf. Bergman & Magnusson, 1997; von Eye & Bergman, 2003). Investigators have shifted the emphasis of their questions from, for example, "What is the antecedent of conduct disorder?" to "What are the factors that initiate and maintain individuals on pathways probabilistically associated with Conduct Disorder and related outcomes?" and "What differentiates those progressing to Antisocial Personality Disorder from those progressing to depression and those being free from maladaptation or a handicapping condition?" As researchers increasingly conceptualize and design their investigations at the outset with the differential pathway concepts of equifinality and multifinality as a foundation, we will come progressively closer to achieving the unique goals of the discipline of developmental psychopathology—to explain the development of individual patterns of adaptation and maladaptation (Cairns, Cairns, Xie, Leung, & Heane, 1998; Cicchetti & Rogosch, 1996; Sroufe & Rutter, 1984).

Likewise, as we have drawn the distinction between factors that initiate pathways and factors that maintain or deflect individuals from pathways, there is a growing recognition of the role of the developing person as a processor of experience. The environment does not simply create an individual's experience; rather, individuals also actively create their experiences and their own environments in a changing world (Cummings et al., 2000; Scarr & McCartney, 1983). Individuals select, integrate, and actively affect their own development and the environment in a dynamic fashion (Bergman & Magnusson, 1997;

Cicchetti & Tucker, 1994; Rutter et al., 1997; Wachs & Plomin, 1991).

The principle of contextualism conceptualizes developmental processes as the ongoing interaction between an active, changing individual and a continuously unfolding, dynamic context (Cicchetti & Aber, 1998; Cummings et al., 2000). Thus, maladaptation and psychopathology are considered to be products of the transaction among an individual's intraorganismic characteristics, adaptational history, and the current context (Boyce et al., 1998; Sroufe, 1997). Moreover, we now know that social contexts exert effects not only on psychological processes, but also on biological structures, functions, and processes (Boyce et al., 1998; Cicchetti, 2002; Cicchetti & Tucker, 1994; Eisenberg, 1995; Nelson & Bloom, 1997).

There also has been a veritable explosion in our knowledge of developmental neurobiology, that area of neuroscience that focuses on factors regulating the development of neurons, neuronal circuitry, and complex neuronal organization systems, including the brain (Ciaranello et al., 1995). In addition, advances in the field of molecular genetics (see Lander & Weinberg, 2000; Lewin, 2004) have contributed to the understanding of neurological disease, allowing scientists for the first time to understand the genetic basis of certain disorders without requiring foreknowledge of the underlying biochemical abnormalities. These accomplishments have helped to engender renewed excitement for the potential contributing role that the field of molecular genetics can play in comprehending the development of psychopathology (Caspi et al., 2002, 2003; Cicchetti & Blender, 2004; Kaufman et al., 2004; Plomin & McGuffin, 2003; Plomin & Rutter, 1998; Rutter & Plomin, 1997; Waldman, 2003).

Developmental psychopathologists have begun to recognize that the milieu in which an individual develops is likely to profoundly influence the course of epigenesis (Boyce et al., 1998; Cicchetti & Aber, 1998; Garcia Coll et al., 2000; Garcia Coll & Vasquez Garcia, 1996; Hoagwood & Jensen, 1997; Richters & Cicchetti, 1993). The dynamic interplay of risk and protective processes may have differential impact depending on the cultural norms, practices, values, and beliefs. Cultures may be characterized on a continuum ranging from sociocentric (emphasizing community, family, and interconnectedness) to individualistic (emphasizing individuality, autonomy, and personal achievement; Garcia Coll et al., 2000; Shweder, 1991). The ideal self correspondingly varies with respect to the degree to which the self is defined in terms of relatedness to others versus in terms of autonomy and achievement. As such, cultural groups will differ in their socialization goals for

desired outcomes for well-functioning members of the culture. Norms for appropriate and inappropriate behavior will have different thresholds, and discipline strategies will vary in accord with what behaviors are regarded as desirable or unacceptable.

For example, Canino and Guarnaccia (1997) noted that psychiatric epidemiological studies have shown that Puerto Rican adolescents exhibit lower rates of Conduct Disorder and substance abuse than adolescents in mainland United States; this difference may be attributable to greater monitoring and supervision of teenagers in the culture, consistent with a more sociocentric emphasis and a more authoritarian parenting orientation, fostering deference to adults and social institutions. Conversely, the high rate of teen pregnancies among Puerto Rican youth (Garcia Coll & Vazquez Garcia, 1996) may suggest that these girls assume more adult-like responsibilities earlier in their lives, thereby decreasing the likelihood of their involvement in conduct disorder and substance-abusing behaviors.

To provide a further illustration of how an individual's cultural milieu may influence the developmental course, Luthar and McMahon (1996) discovered that inner-city youth whose peer relationships were aggressive nonetheless were popular with their peers. Thus, in addition to the more typical pathway to peer popularity (i.e., prosocial behaviors, academic success), Luthar and McMahon identified a less typical pathway characterized by disruptive and aggressive behaviors and poor academic functioning. They hypothesized that within the crime-, violence-, and poverty-laden disenfranchised communities where these youth reside, aggressive behaviors that are viewed as deviant by the mainstream may be associated with prestige and high status among particular socioeconomic groups (cf. Richters & Cicchetti, 1993).

Moreover, risk and protective processes and the manner in which they transact may vary depending on priorities of the culture. Consequently, the individual's response to an event, as well as the reactions of other members of the culture, will influence the salience of the event and how it is responded to. Culture also may influence the mode of symptom expression. Cultural values, beliefs, and practices may tend to suppress manifestation of distress in one domain (e.g., socioemotional), while tolerating the expression in another domain (e.g., physical; Weisz, Weiss, Alicke, & Klotz, 1987). For example, Serafica (1997) noted a tendency for physical manifestations of distress to be tolerated among Asian American families, as compared with less acceptance of psychological expression.

Immersion in the mainstream culture by immigrating adolescents from other cultures is likely to generate signif-

icant difficulties in adaptation, particularly if the values of the home culture are in conflict with those in the mainstream culture (Canino & Guarnaccia, 1997). Acculturation pressures may generate stress for youths as they bridge two cultural worlds. Similarly, individuals from existing subcultures nested within the broader American culture may experience conflicts when the meaning they attribute to behaviors and events is at odds with the mainstream cultural prescriptions. Thus, culture must be incorporated into how developmental psychopathologists conceptualize causal processes influencing the developmental course and how adaptation and psychopathology are defined (Flores, Cicchetti, & Rogosch, 2005; Garcia Coll et al., 2000; Hoagwood & Jensen, 1997).

HISTORICAL ROOTS OF DEVELOPMENTAL PSYCHOPATHOLOGY

The field of developmental psychopathology first came into ascendance during the 1970s, predominantly through being highlighted as an important perspective by researchers conducting prospective longitudinal studies of children at risk for becoming schizophrenic (Watt, Anthony, Wynne, & Rolf, 1984). Also instrumental in the field's emergence were epidemiological investigations of families exhibiting discord, disharmony, and disruption but where there was no parental mental disorder (Rutter & Quinton, 1984) and studies of the links between cumulative risk factors and developmental outcome (Sameroff, Seifer, Barocas, Zax, & Greenspan, 1987). Likewise, research on the causes, correlates, and consequences of secure and insecure attachment (Ainsworth, Blehar, Waters, & Wall, 1978; Sroufe, 1983; Sroufe, Carlson, Levy, & Egeland, 1999), investigations of children with a variety of handicapping conditions (Cicchetti & Pogge-Hesse, 1982; Cicchetti & Sroufe, 1976, 1978; N. O'Connor & Hermelin, 1978), and studies in life span developmental psychology (Baltes, Reese, & Lipsitt, 1980) were influential in furthering interest in developmental psychopathology.

It was not until the last several decades of the twentieth century that the discipline of developmental psychopathology began to exert a major impact on the manner in which researchers studied children and adults with high-risk conditions and mental disorders (see, e.g., Cicchetti, 1984a; Cicchetti & Richters, 1997; Rutter, 1986; Rutter & Garmezy, 1983; Sroufe & Rutter, 1984; Zigler & Glick, 1986). Conceptualizations of the nature of mental disorder, etiological models of risk and psychopathology, the scientific questions that were posed, and the design and data analytic strategies were reexamined, challenged, and

cast in a new light by developmental psychopathologists (Cicchetti & Hinshaw, 2003; Cicchetti & Richters, 1997; Granic & Hollenstein, 2003; Richters, 1997; Richters & Cicchetti, 1993; Rutter & Sroufe, 2000; Sroufe, 1989; Wakefield, 1992, 1997).

The field of developmental psychopathology owes its emergence and coalescence to a number of historically based endeavors in a variety of disciplines, including embryology, genetics, the neurosciences, philosophy, sociology, and clinical, developmental, and experimental psychology (see Cicchetti, 1990, for an elaboration). As is the case in tracing the pathways to discovery in clinical medicine, the influences of these diverse disciplines on the field of developmental psychopathology illustrate the manner in which advances in our knowledge of developmental processes and within particular scientific domains mutually inform each other. Notably, a number of the major theoretical systematizers in these diverse scientific fields depicted psychopathology as a distortion or exaggeration of the normal condition and reasoned that the study of normal biological, psychological, and social processes could be more clearly understood through the investigation of pathological phenomena (Cicchetti & Cohen, 1995c).

A basic theme appears in the writings of these earlier thinkers: Because all psychopathology can be conceived as a distortion, disturbance, or degeneration of normal functioning, it follows that, if one wishes to understand pathology more fully, then one must understand the normal functioning against which psychopathology is compared (Cicchetti, 1984b). Not only is knowledge of normal biological, psychological, and social processes very helpful for understanding, preventing, and treating psychopathology (Cicchetti & Hinshaw, 2002; Cicchetti & Toth, 1992; Toth & Cicchetti, 1999), but also the deviations from and distortions of normal development that are seen in pathological processes indicate in exciting ways how normal development may be better investigated and understood (Baron-Cohen, Tager-Flusberg, & Cohen, 1993; Cicchetti, 2003; Freud, 1965; Sroufe, 1990). Similarly, information obtained from investigating psychopathology can augment the comprehension of normal development (Cicchetti, 1984b, 1993, 2003; Rutter, 1986; Rutter & Garmezy, 1983; Sroufe, 1990; Weiss, 1969).

Since the nineteenth century, research in embryology has provided a rich empirical foundation for the emergence of organismic theories of development that possess great significance for comprehending the emergence and course of adaptive and maladaptive functioning (see, e.g., Cairns, 1983; Fishbein, 1976; Sameroff, 1983; Waddington, 1957; Weiss, 1969). From the research programs of such major

embryologists as Hans Spemann (1938; Kuo, 1939, 1967), the principles of differentiation in development, a dynamically active organism and of a hierarchically integrated system that were later used in the investigation of the processes contributing to abnormal development within the neurosciences, psychology, and experimental psychopathology were derived (Cicchetti, 1990). Within the field of neurology, Santiago Ramon y Cajal (1893, 1937) utilized embryos to study the developing nervous system; he demonstrated that nerve cells possess terminal structures that contact with other nerve cells but do not fuse with them (i.e., that the nerve fibers are contiguous rather than continuous), thereby providing additional empirical support for the existence of a hierarchically integrated nervous system.

One of the most dominant ideas that contributed to the blossoming of the developmental perspective was Herbert Spencer's (1862/1900) "developmental hypothesis," in which ontogenesis was depicted as a uniform process that was governed by universal laws and principles (see also J. A. Glick, 1992; Kaplan, 1967). Throughout the ensuing period, the maturation of developmental psychology as a discipline has exerted a profound effect on the field of developmental psychopathology. The advances made in our knowledge of basic neurobiological, perceptual, cognitive, linguistic, representational, social, social-cognitive, emotional, and motivational domains have provided a firm empirical basis against which developmental psychopathologists could discover new truths about the processes underlying adaptation and maladaptation, as well as the best means of preventing and treating psychopathology (Cicchetti & Toth, 1998). Moreover, the influences of clinical psychology, psychiatry, and developmental psychopathology can be seen increasingly in the research ideas of developmental psychologists (Parke, 2004).

Writing in the late 1970s, Eisenberg (1977) urged his psychiatric colleagues to adopt a developmental framework, presenting it as a helpful unifying perspective that would enable clinical investigators to frame the difficulties they encounter in investigating and treating psychopathology. Eisenberg believed that the concept of development could serve as "the crucial link between genetic determinants and environmental variables, between . . . psychology and sociology, [and between] . . . 'physiogenic and psychogenic' causes" (p. 225). Moreover, he proposed that the term *development* be used in a broad sense and that it include "not only the roots of behavior in prior maturation as well as the residual of earlier stimulation, both internal and external, but also the modulations of that behavior by the social fields of the experienced present" (p. 225).

As developmental psychology has evolved toward becoming an ever more applied area of specialization (Shonkoff, 2000), field placements, research opportunities in diverse settings, and exposure to a range of cultural, racial, and ethnic groups are becoming more commonplace in doctoral training programs. Moreover, the growing recognition of the need to integrate developmental psychology with other scientific fields has contributed to the influx of training opportunities in settings as diverse as day care centers, family court, detention centers, mental health clinics, early intervention programs, and schools (Zigler, 1998).

An outgrowth of the attention to applied and policy-relevant issues that has obvious connections with a developmental psychopathology perspective is that scientists have developed an appreciation for the diversity of patterns of individual and family development that exist across cultures and settings (Cicchetti & Aber, 1998; Crick & Zahn-Waxler, 2003; Davies & Cicchetti, 2004; Garcia Coll et al., 1996, 2000; Swanson et al., 2003). Diversity based on ethnicity, gender, race, culture, handicap, and psychopathology was long ignored by researchers in mainstream academic developmental psychology. Now that we are accruing more knowledge about diversity in development, we are learning that the same rules of normal ontogenesis do not necessarily exist for, or apply to, all children and families (see, e.g., Baldwin, Baldwin, & Cole, 1990; Davies & Cicchetti, 2004; Garcia Coll et al., 1996; Karmiloff-Smith, 1998; Rutter & Sroufe, 2000). Without a sophisticated understanding of the range of diversity in normal development, we would be severely hampered in our attempts to elucidate the pathways to adaptation and maladaptation in high-risk and disordered individuals of varying backgrounds. Thus, developmental psychology has been integral to fostering the emergence of developmental psychopathology.

There also have been a number of landmark publications that have given great momentum to the developmental perspective on psychopathology. Included among these are Anna Freud's (1965) *Normality and Pathology in Childhood*, Santostefano and Baker's (1972) and Kohlberg, LaCrosse, and Rick's chapters in the *Manual of Child Psychopathology* (Wolman, 1972), Garnezy's (1974a, 1974b) articles on high-risk research in the *Schizophrenia Bulletin*, and Achenbach's (1974) textbook, *Developmental Psychopathology*. In addition, Santostefano's (1979) book, *A Biodevelopmental Approach to Clinical Child Psychology*, Rutter's (1980) volume, *Scientific Foundations of Developmental Psychiatry*, Rutter and Garnezy's (1983) chapter in the *Handbook of Child Psychology*, and the special issue on developmental psychopathology, considered by many to

mark the modern-day emergence of the field, published in *Child Development*, the premiere journal on normal development (Cicchetti, 1984a), all played a major role in advancing the developmental psychopathology perspective. Over the past several decades, a symposium series on developmental psychopathology was initiated (Cicchetti, 1989), a journal devoted to theory and research on developmental psychopathology, *Development and Psychopathology*, published its inaugural issue in 1989, and numerous special issues have been devoted to topics in developmental psychopathology. Finally, the publication of the first edition of the present volumes (Cicchetti & Cohen, 1995a, 1995b) and the inclusion of a chapter on developmental psychopathology in each of the past two editions of the *Handbook of Child Psychology* (Cicchetti & Toth, 1998, in press) attest to the significant growth of the discipline.

DEFINITIONAL PARAMETERS OF DEVELOPMENTAL PSYCHOPATHOLOGY

Multiple theoretical perspectives and diverse research strategies and findings have contributed to the emergence of the field of developmental psychopathology. A wide range of content areas, scientific disciplines, and methodologies have been germane (Cicchetti & Hinshaw, 2003; Cicchetti & Richters, 1997). Risk factors and protective factors have been established at multiple levels of analysis and in multiple domains. Various researchers have convincingly demonstrated that risks may be genetic, biochemical, physiological, cognitive, affective, experiential, intrafamilial, socioeconomic, social, or cultural (Caspi et al., 2002, 2003; Cicchetti & Aber, 1986; Cicchetti & Blender, 2004; Cicchetti & Sroufe, 2000). Contributions to the field of developmental psychopathology have come from many areas of the social and biological sciences.

It cannot even be stated a priori that a particular piece of research is or is not relevant to a developmental psychopathology perspective. An investigation of a single age group—even adults, for example—may be useful for resolving a perplexing methodological conundrum or revealing a new approach that brings about a series of critical new developmental studies. Likewise, some longitudinal studies of infants, children, adolescents, and adults may be so poorly conceived that they shed little light on development or psychopathology. In essence, we eschew an orthodoxy that states that some types of studies are part of the domains of developmental psychopathology, whereas others are not. Thus, we believe that a “big tent,” multidisciplinary approach to the investigation of the relation between normality and psychopathology offers the most promise for

advancing our knowledge of normal and abnormal developmental processes.

At the same time, a core identity for the field can be defined, manifest in a set of issues and perspectives, that makes it possible to set research directions. Central, of course, is the emphasis given to discovering processes of development, with the goal of comprehending the emergence, progressive unfolding, and transformation of patterns of adaptation and maladaptation over time. Based on this perspective, it is possible to evaluate our current understanding of psychopathology in general, as well as more particular problems of functioning. Although it is hazardous to say a particular study is or is not an example of developmental psychopathology (because one must consider the longer, more programmatic view of the research), it is possible to look at work in the field in terms of progress toward a developmental understanding. We can ask, for example, how evolved is our developmental understanding of child maltreatment, conduct problems, depression, Bipolar Disorder, or Schizophrenia. We can examine work with regard to promoting such a developmental understanding, and we can suggest the kinds of studies needed to move us toward an understanding of developmental processes.

Developmental psychopathology refers not simply to the search for the indicators or predictors of later disturbance, though these are of interest, but also to the description of the interactive processes that lead to the emergence and guide the course of disturbed behavior. In trying to understand why individuals react as they do, some researchers will emphasize one set of initiating and maintaining conditions, whereas others will argue that such factors must be examined in developmental studies, not simply be taken as givens. Increasingly, interdisciplinary multiple-levels-of-analysis investigations must assume ascendancy in the field of developmental psychopathology.

CONCEPTUAL ISSUES AND PRINCIPLES

To elaborate more completely on the definitional parameters that undergird the field of developmental psychopathology, we now turn to an in-depth explication of its major conceptual issues and principles. Our delimitation of the principles is not presented in any presumed order of importance, nor is it meant to be an all-inclusive list.

Risk and Protective Factors

It is instructive to consider the role of risk factor research in answering etiological questions about the emergence of psychopathology. Depending on the stage of research, an

association between a factor or characteristic and a psychopathological outcome will indicate increasing levels of specificity regarding the degree to which the factor suggests or constitutes causal processes contributing to a psychopathological outcome (Kazdin, Kraemer, Kessler, Kupfer, & Offord, 1997; Kraemer et al., 1997; Kraemer, Stice, Kazdin, Offord, & Kupfer, 2001). Establishing that a putative risk factor operates at the same point in time as a psychopathological outcome allows for the putative risk factor to be regarded as a correlate of the disorder. Because of the concurrent assessment of the putative risk and the outcome, it is not possible to determine if the putative risk contributed to the negative outcome or whether the negative outcome led to the putative risk factor. For example, determining that a substance-abusing adolescent has friends who also abuse drugs tells the researcher only that drug abuse and drug-abusing friends are correlated. It is not possible to differentiate whether drug use is a consequence of associating with drug-using peers or whether individuals who use drugs seek out peers who also use drugs. Similarly, if depression and substance abuse are assessed as co-occurring at a single point in time, then it is not possible to ascertain whether depression contributes to substance abuse or whether substance abuse contributes to depression.

To establish a construct as a risk factor for negative outcome, it is necessary to determine that the putative risk was present prior to the emergence of the negative outcome. Thus, a risk factor allows for prediction of a later outcome. Knowing that a child exhibits a disruptive behavior disorder or that a child's parent is an alcoholic allows one to predict that there is greater risk for the child to subsequently exhibit drug use problems. The risk factor implies greater potential; it is probabilistic risk, and not all individuals who exhibit the risk factor will develop the negative outcome (see, e.g., Cicchetti & Rizley, 1981; Kraemer et al., 2001; Luthar, Cicchetti, & Becker, 2000; Zubin & Spring, 1977).

Although the determination of risk factor status due to temporal precedence is an advance over knowledge of a variable as a correlate, knowing that a construct serves as a risk factor does not establish that the construct operates to cause the negative outcome. The next phase of research necessary to move toward an etiological understanding of maladaptive psychopathological outcomes is to differentiate between risk indicators and risk mechanisms (T. G. O'Connor & Rutter, 1996). Risk mechanisms specify the processes through which risk factors operate to generate an outcome. Kraemer and colleagues (1997) strove to further define risk factors as either markers or causal risk factors. *Markers* are risk factors that are not causally involved in

determining outcomes. Markers are either *fixed* (factors that cannot be changed, such as sex or premature birth) or *variable* (features that spontaneously change, such as age, or that may be modified, such as through intervention). If changing a variable marker results in change in the potential for a negative outcome, then the variable marker is implicated as a *causal risk factor*.

Despite the fact that markers are not involved in causing a negative outcome, they are valuable in terms of elucidating potential processes that do have causal impact on outcomes. A marker may contribute to delineating a third factor that contributes directly to both the marker and the negative outcome. Discovering causal factors that contribute to the marker may result in identifying causal risk factors that operate to produce the psychopathological outcome. Markers thus have a spurious relation to outcomes yet may be valuable in clarifying causal mechanisms. For example, if dropping out of school is related to subsequent increases in drug use, then dropping out of school would be implicated as a risk factor for drug use. If an intervention were applied to decrease dropping out of school and no differential impact on drug use was obtained, then the association between school dropout and increased drug use would be spurious, and dropping out of school would be regarded as a variable marker. Some other factor contributing to both school dropout and drug use may be implicated. For example, Conduct Disorder could potentially be a third variable that contributes to both school dropout and drug use, thereby accounting for the spurious relation between school dropout and increased drug use.

In contrast, if an intervention to reduce school dropout decreases subsequent drug use, then dropping out of school would be implicated as a causal risk factor for drug use. The research process thus would have moved further to identifying a cause of drug use. Nevertheless, the identification of a causal risk factor does not imply that the cause of a negative outcome has been ascertained. The causal mechanism (or one of them) remains to be identified. However, school dropout would be involved in some way with the causal mechanism. A delineation of other causal risk factors could provide direction for the causal source through determining the ways multiple causal risk factors are interrelated. In so doing, a common element may be ascertained that may carry more explanatory power as the causative risk mechanism. Thus, it is necessary for research to proceed in stages to progressively isolate risk mechanisms from myriad correlates, risk factors, markers, and causal risk factors.

Mental disorders are likely to be caused by multiple processes rather than singular causes (Cicchetti & Sroufe,

2000; Institute of Medicine, 1994). Thus, the identification of a causal risk factor will contribute to elucidating only one aspect of a more complex matrix of causes. Within individuals, there are likely to be multiple component processes rather than unitary causes that contribute to psychopathological outcomes (Cicchetti & Blender, 2004). Moreover, different individuals are likely to develop the same mental disorder through different constellations of processes. Thus, attention to identification of multiple risk mechanisms is important. Within individuals, single risk processes may not have sufficient power to eventuate in a mental disorder on their own. However, their impact might become more potent as they are combined with additional sources of risk. Collectively, multiple risk processes may operate additively, amassing greater potential that psychopathology will ensue. Additionally, risk processes may co-act synergistically with an exponential rather than additive impact on increasing the potential for maladaptive or psychopathological outcomes (cf. Rutter, 1990). Risk factors tend to co-occur rather than occur in isolation (Rutter, 1990; Sameroff et al., 1987). Some risk factors may contribute to the development of other problems that, in turn, become risk factors for other mental disorders as development proceeds.

The operation of risk processes must further be considered in the context of protective factors that the developing individual also may experience. Protective processes function to promote competent development and reduce the negative impact of risk processes (Luthar et al., 2000). Thus, protective factors may counterbalance the impact of risk processes, thereby decreasing the likelihood that the risk process will eventuate in maladaptive or psychopathological outcomes (Cicchetti & Aber, 1986; Luthar et al., 2000). For example, the impact on later substance use of neurodevelopmental anomalies that are consequences of maternal drug abuse may be reduced for children placed in adoptive homes in which structure, active engagement, warmth, and closeness are provided. These protective processes may dilute the potential of the neurodevelopmental anomaly to contribute to a substance abuse outcome. Alternatively, protective factors may operate in an interactive manner: The protective factor may reduce a negative outcome within a high-risk group but have limited impact within a low-risk group. For example, in considering parental alcoholism as a risk factor for adolescent substance abuse, high parental monitoring may be particularly valuable in reducing adolescent substance use in families without an alcoholic parent. In contrast, in families without an alcoholic parent, the degree of parental monitoring may be unrelated (or less strongly related) to adolescent

substance use. Thus, as a protective factor, parental monitoring would be particularly important in reducing negative outcomes only within the group in which the risk processes associated with parental alcoholism have the potential to operate. Consequently, understanding the etiologic role of risk processes on substance abuse outcomes must occur within a wider framework that also incorporates investigation of processes that may protect the individual from negative outcomes through counterbalancing or diluting the impact of risk factors.

It is essential to realize that risk factors do not function in a static manner. Rather, over the course of development, there is an ongoing dynamic progression among the various risk processes involved in shaping the developmental course of the individual and contributing to maladaptive and psychopathological outcomes. Cicchetti (1999; Cicchetti & Lynch, 1993; Cicchetti & Toth, 1998) has drawn attention to the importance of conceptualizing risk and protective factors in an ecological-transactional developmental model. At each level of the ecology, risk and protective factors may operate in tandem, transacting with features of the individual (i.e., the current organization of biological, emotional, cognitive, representational, and interpersonal development). Not only do external factors influence the development of the individual, but also the individual exerts influence on the external levels of the ecology, including family members, peers, and the school environment. Patterns of influence are thus mutual, as development proceeds with ongoing transactions between the individual and the external world.

Additionally, transactions occur among the different internal domains for the individual (i.e., biological, cognitive, affective, representational, and interpersonal). Not only do biological processes (e.g., genetic predispositions, neurodevelopmental anomalies) influence domains of psychological functioning, but also psychological experience, in turn, influences biological structure and function (Cicchetti & Tucker, 1994; Eisenberg, 1995). The quality of the transactions of mutual influence within the individual and between the individual and the external world shapes the character of individual development, and different developmental pathways ensue. Most important, the dynamic balance of risk and protective processes that operate over the course of development structures the developmental pathways in which individuals engage, with a progression of high risk and few protective resources engendering greater vulnerability and incompetence in the individual, contrasting with relative competence attained among individuals who experience fewer risks and numerous protective, growth-enhancing resources. Accordingly,

understanding the roots of vulnerability to mental disorder requires moving beyond features of the current context when these problems emerge to articulating the course of development that individuals have experienced and how risk and protective processes have structured the organization of the individual.

Contextual Influences

Developmental psychopathologists have been cognizant of the importance of contextual influences in defining what constitutes abnormality. Clearly, no behavior or pattern of adaptation can be viewed as pathological except in particular contexts (Cicchetti & Schneider-Rosen, 1986; Luthar & McMahon, 1996; Richters & Cicchetti, 1993; Werner & Kaplan, 1963). Further, chronological age and developmental stage or level of biological and psychological organization are important defining features of context for clinicians and researchers interested in chronicling the development of mental disorders.

Although there is a growing awareness that contextual factors play an important role in defining phenomena as psychopathological (Jensen & Hoagwood, 1997; Richters & Cicchetti, 1993; Wakefield, 1992), there are vast differences in how the contexts for human development are conceptualized. Bronfenbrenner's (1979) articulation of nested levels in the ecology of human development marked a great stride forward to conceptualizing contexts. The macro-, exo-, meso-, and microsystems delimited by Bronfenbrenner clearly and powerfully alert the developmental psychopathologist to important and vastly different sources of contextual influence on individual development.

Situational and interpersonal influences operate at the microsystem level in Bronfenbrenner's (1979) schema and have been the traditional focus of psychological study. However, it has thus far proven to be far more difficult to conceptualize specific macro-, exo-, and mesosystem influences on development. Part of the difficulty in pinpointing the effects of these more distal contexts is that documenting their impact on individual development requires cross-fertilization with the disciplines that study these macro phenomena: anthropology, demography, sociology, economics, and epidemiology. Parental workplace, school transitions, violent communities, persistent poverty, and unsupportive stress-laden ecologies are all examples of contexts that exert influence on the development of psychopathology in children and adults (Brooks-Gunn, Duncan, & Aber, 1997; Cicchetti & Toth, 1997; Eccles, Lord, & Roeser, 1996; Luthar, 1999; Lynch & Cicchetti, 1998; Richters & Martinez, 1993). Consequently, societal-,

community-, and institutional-level influences on individual development are now beginning to be examined in systematic, rigorous, empirical fashion. Now that the field of developmental psychopathology has begun to incorporate a multiple-levels-of-analysis perspective (Cicchetti & Blender, 2004; Cicchetti & Dawson, 2002), it will become more common for scientists investigating contextual aspects of problem behaviors and mental disorders to include assessments of higher levels of contexts into their research armamentaria (Boyce et al., 1998; Cicchetti & Aber, 1998).

The Mutual Interplay between Normality and Psychopathology

A focus on the boundary between normal and abnormal development is central to a developmental psychopathology perspective. Such a viewpoint emphasizes not only how knowledge from the study of normal development can inform the study of high-risk conditions and mental disorders, but also how the investigation of risk and pathology can enhance our comprehension of normal development (Cicchetti, 1984b, 1990; Sroufe, 1990).

Before the field of developmental psychopathology could emerge as a distinct discipline, the science of normal development needed to mature, and a broader basis of firm results had to be acquired. As dramatic gains in developmental neurobiology, neuroimaging, and molecular genetics have occurred, in concert with an increased comprehension of hormonal, emotional, social, social-cognitive, and representational processes, we now possess a much stronger ability to utilize knowledge of normative development as a yardstick against which to measure psychopathology.

The central focus of developmental psychopathology involves the elucidation of developmental processes and how they function, as indicated and elaborated by the examinations of extremes in the distribution (i.e., individuals with psychopathology). Developmental psychopathologists also direct attention toward variations in the continuum between the mean and the extremes. These variations may represent individuals who are currently not divergent enough to be considered disordered but who may progress to further extremes as development continues. Such individuals may be vulnerable to developing future disordered outcomes, or developmental deviations may, for some individuals, reflect either the earliest signs of an emerging dysfunction or an already existing dysfunction that is partially compensated for by other processes within or outside the individual.

Because of the interrelations between the investigation of normal and abnormal development, developmental psy-

chopathologists must be cognizant of normal pathways of development within a given cultural context (Garcia Coll et al., 1996), uncover deviations from these pathways, articulate the developmental transformations that occur as individuals progress through these deviant developmental courses, and identify the processes and mechanisms that may divert an individual from a particular pathway and onto a more or less adaptive course (Cicchetti & Aber, 1986; Cicchetti & Rogosch, 1996; Sroufe, 1989).

Developmental psychopathologists have long argued that one gains valuable information about an organism's normal functioning through studying its abnormal condition. Relatedly, developmental psychopathologists have asserted that theories of normal development can be affirmed, challenged, and augmented by incorporating knowledge about atypical development. As Werner (1948, p. 23) has stated, "A whole series of mental diseases are important to developmental psychology in that they represent the regression, the dissolution, of the higher mental processes, or inhibitions of the genetically advanced levels." Furthermore, Werner believed that because

psychopathology will shed light on the genetic data of other developmental fields . . . the results of psychopathology . . . become valuable in many ways for the general picture of mental development, just as psychopathology is itself enriched and its methods facilitated by the adoption of the genetic approach. (p. 33–34)

Despite the fact that developmental psychopathologists emphasize the mutual interplay between normal and atypical development, most contemporary theory and research have focused on the contributions that normal development can make to advancing our knowledge of psychopathological processes. There has been significantly less recognition that the investigation of high-risk conditions and mental disorders can augment our comprehension of normal developmental processes; however, this is beginning to change (see, e.g., Cicchetti, 1996, 2003).

Understanding how psychopathological conditions evolve and how aberrations of component developmental systems that exist among disordered individuals eventuate may be informative for elucidating critical components of development that are not typically evident (Chomsky, 1968; Cicchetti, 2003; Lenneberg, 1967; T. G. O'Connor, 2003). Often, the examination of a system in its smoothly operating normal or healthy state does not afford us the opportunity to comprehend the interrelations among its component subsystems. In usual circumstances, the integration of component developmental systems may be so well established

that it is difficult to determine how normal functioning is dependent on this confluence. When there is a clear aberration or deficit in a component system within a disordered population, examination of how that atypicality relates to the organization of other component systems can reveal information regarding the interdependency of components not readily apparent under normal conditions (Cicchetti & Sroufe, 1978). Thus, the interest of developmental psychopathologists in the convergences and divergences between normality and psychopathology can be mutually beneficial for understanding development across the range of variation (Cicchetti & Cohen, 1995c; Sroufe, 1990). As M. Glick (1997, p. 242) has explicated: "Just as normative developmental principles have been instrumental for elucidating many facets of psychopathology, findings from . . . research with disordered adults and with children and adolescents having special needs have enhanced understanding of normal processes."

"Experiments of nature" are "naturally arising conditions in which there is a possibility of separating otherwise confounding processes or opportunities to examine processes that for ethical or practical reasons would not have been possible" (T. G. O'Connor, 2003, p. 837). Because they enable us to isolate the components of the integrated system, investigation of these natural experiments sheds light on the normal structure of the system. If we choose to ignore or bypass the investigation of these experiments of nature, we are likely to construct theories that will eventually be contradicted by critical discoveries in research on psychopathology (Lenneberg, 1967). The utilization of diversity of natural experiments is critical because, when extrapolating from nonnormal populations with the goal of informing developmental theory, it is important that a range of populations and conditions be considered. To make generalizations beyond the risk process or mental disorder investigated, it is necessary to examine an entire spectrum of disordered modifications.

Historically, experiments of nature have been utilized in a variety of disciplines to contribute to the normal understanding of the phenomena under investigation (Cicchetti, 1990; for work in basic medicine, see, e.g., McQuarrie, 1944). As Good and Zak (1956) noted, one value of incorporating experiments of nature into our research armamentaria is that these natural experiments enable observations and discoveries that would be extremely difficult, if not impossible, to duplicate in the laboratory setting. Theoreticians and researchers in a number of fields, including genetics, embryology, neurology, neuropsychology, psychiatry, and clinical and developmental psychology, have examined experiments of nature to elucidate theory and research

in their respective disciplines (Goldstein, 1939; Inhelder, 1943/1968; Jackson, 1884/1958; Lenneberg, 1967; Luria, 1966/1980; Meyer, 1934, 1957; Shakow, 1967; B. Tizard Hodges, 1978; J. Tizard & Tizard, 1971; Weiss, 1939, 1961). Research in immunobiology likewise has a long history of utilizing experiments of nature to elucidate basic mechanisms in the functioning of the immune system (Good, 1991; Good & Zak, 1956; Sanna & Burton, 2000; Smith, 2000). Moreover, in recent decades, Rutter (1994, 2000; Rutter, Pickles, Murray, & Eaves, 2001) has eloquently articulated ways in which natural experiments are useful for the testing of causal hypotheses on the causes and courses of psychopathology.

The examination of individuals with high-risk conditions and mental disorders can provide a natural entrée into the study of system organization, disorganization, and reorganization that is otherwise not possible due to the constraints associated with research involving human participants. Through investigating a variety of high-risk and mentally disordered conditions, it is possible to gain significant insight into processes of development not generally achieved through sole reliance on investigations of relatively homogeneous nondisordered populations. Research conducted with atypical populations also can elucidate the behavioral and biological consequences of alternative pathways of development, provide important information about the range and variability of individual response to challenge and adversity, and help to specify the limits of behavioral and biological plasticity (Baron-Cohen, 1995; Cicchetti, Rogosch, Maughan, Toth, & Bruce, 2003; Damasio, Grabowski, Frank, Galaburda, & Damasio, 1994; Fries & Pollak, 2004; Gunnar et al., 2001). Finally, findings proffered by experiments of nature also hold considerable promise for informing prevention and intervention strategies (Cicchetti & Hinshaw, 2002).

DEVELOPMENTAL PATHWAYS

Since its inception as an emergent interdisciplinary science, diversity in process and outcome has been conceived as among the hallmarks of the developmental psychopathology perspective. As Sroufe (1990, p. 335) has asserted, "One of the principal tasks of developmental psychopathology is to define families of developmental pathways, some of which are associated with psychopathology with high probability, others with low probability." Even before a mental disorder emerges, certain pathways signify adaptational failures that probabilistically forebode subsequent psychopathology (Sroufe, 1990). Thus, developmental psychopathologists have articulated the expectation that there

are multiple contributors to adaptive and maladaptive outcomes in any individual, that these factors and their relative contributions vary among individuals, and that there are myriad pathways to any particular manifestation of adaptive and disordered behavior (Cicchetti, 1993; Robins, 1966; Robins & Rutter, 1990; Sroufe & Jacobvitz, 1989). In addition, it is believed that there is heterogeneity among individuals who develop a specific disorder with respect to the features of their disturbance, as well as among individuals who evidence maladaptation but do not develop a disorder. In accord with this view, the principles of equifinality and multifinality derived from general systems theory (von Bertalanffy, 1968) are germane.

Equifinality refers to the observation that in any open system (cf. Mayr, 1964, 1988), a diversity of pathways, including chance events or what biologists refer to as non-linear epigenesis, may lead to the same outcome. Stated differently, in an open system (i.e., one where there is maintenance in change, dynamic order in processes, organization, and self-regulation), the same end state may be reached from a variety of different initial conditions and through different processes. This is referred to as equifinality, an organismic process that possesses significant implications for biological and psychological regulatory systems and for behavioral and biological plasticity (Cicchetti & Tucker, 1994; Curtis & Cicchetti, 2003). In contrast, in a closed system, the end state is inextricably linked to and determined by the initial conditions. If either of the conditions change or the processes are modified, then the end state also will be modified (von Bertalanffy, 1968).

Initial descriptions of equifinality emanated from work in embryology. For example, the development of a normal organism was shown to occur from a whole ovum, a divided ovum, or two fused ova. Further, it was demonstrated that different initial sizes and different courses of growth can eventuate in the same ultimate size of an organism (von Bertalanffy, 1968; Waddington, 1957). Within the discipline of developmental psychopathology, equifinality has been invoked to explain why a variety of developmental pathways may eventuate in a given outcome, rather than expecting a singular primary pathway to the adaptive or maladaptive outcome.

The principle of multifinality (Wilden, 1980) suggests that any one component may function differently depending on the organization of the system in which it operates. Multifinality states that the effect on functioning of any one component's value may vary in different systems. Actual effects will depend on the conditions set by the values of additional components with which it is structurally linked. Consequently, the pathology or health of a system

must be identified in terms of how adequately its essential functions are maintained. Stated differently, a particular adverse event should not necessarily be seen as leading to the same psychopathological or nonpsychopathological outcome in every individual. Likewise, individuals may begin on the same major pathway and, as a function of their subsequent "choices," exhibit very different patterns of adaptation or maladaptation (Cicchetti & Tucker, 1994; Rutter, 1989; Sroufe, 1989; Sroufe, Egeland, & Kreutzer, 1990).

A pathways approach builds on knowledge gained from variable-oriented studies; however, attention is shifted to exploring the common and the uncommon outcomes, as well as alternative routes by which outcomes are achieved by different individuals (cf. Cicchetti & Schneider-Rosen, 1986). Thus, what might be considered error variance at the group level must be critically examined for understanding diversity in process and outcome. The emphasis on person-centered observation highlights the transition from a focus on variables to a focus on individuals, and this transition is essential for demonstrating equifinality and multifinality in the developmental course. The examination of patterns of commonality within relatively homogeneous subgroups of individuals and concomitant similarity in profiles of contributory processes becomes an important data analytic strategy. Moreover, the need to examine the totality of attributes, psychopathological conditions, and risk and protective processes in the context of each other rather than in isolation is seen as crucial for understanding the course of development taken by individuals. For example, the presence of a childhood depressive disorder has different developmental implications depending on whether it occurs alone or in conjunction with Conduct Disorder. Similarly, the nature of alcoholism varies considerably depending on differences in the life course of antisociality. Thus, this orientation highlights the importance of an organizational view of development (cf. Cicchetti, 1993; Cicchetti & Sroufe, 1978; Sroufe et al., 1990; Waters & Sroufe, 1983). The meaning of any one attribute, process, or psychopathological condition needs to be considered in light of the complex matrix of individual characteristics, experiences, and social-contextual influences involved, the timing of events and experiences, and the developmental history of the individual.

This attention to diversity in origins, processes, and outcomes in understanding developmental pathways does not suggest that prediction is futile as a result of the many potential individual patterns of adaptation (Sroufe, 1989). There are constraints on how much diversity is possible, and not all outcomes are equally likely (Cicchetti & Tucker, 1994; Sroufe et al., 1990). Nonetheless, the appreciation of

equifinality and multifinality in development encourages theorists and researchers to entertain more complex and varied approaches to how they conceptualize and investigate development and psychopathology. Researchers should increasingly strive to demonstrate the multiplicity of processes and outcomes that may be articulated at the individual, person-oriented level within existing longitudinal data sets. Ultimately, future endeavors must conceptualize and design research at the outset with these differential pathways concepts as a foundation. In so doing, progress toward achieving the unique goals of developmental psychopathology to explain the development of individual patterns of adaptation and maladaptation will be realized (cf. Sroufe & Rutter, 1984).

Multiple Levels of Analysis

Over the course of the past several decades, it has been increasingly acknowledged that the investigation of developmental processes, both normal and abnormal, is an inherently interdisciplinary enterprise (Pellmar & Eisenberg, 2000). Scientists must utilize different levels and methods of analysis depending on the questions being addressed in their research. Although some problems are best handled with the methods and concepts of a single discipline, other issues require interdisciplinary integration. In fact, history reveals that disciplines themselves often evolve from interdisciplinary efforts. For example, neuroscience developed as scientists working in a number of different fields began to work in concert to solve some of the common scientific mysteries that existed about the nervous system (Cowan, Harter, & Kandel, 2000). As knowledge flourishes and as new questions are posed that must be addressed, additional fields continue to be integrated into the dynamic discipline of neuroscience.

Since its inception, developmental psychopathology has been conceived as an interdisciplinary science (Cicchetti, 1990; Cicchetti & Toth, 1991). A number of influential theoretical perspectives, including the organizational perspective (Cicchetti & Schneider-Rosen, 1986; Cicchetti & Sroufe, 1978; Sroufe, 1979, 1997) and Gottlieb's notions of probabilistic epigenesis (Gottlieb, 1991; Gottlieb & Halpern, 2002), have long advocated the importance of multidomain, interdisciplinary research.

Nonetheless, most of what is known about the correlates, causes, pathways, and sequelae of mental disorders has been gleaned from investigations that focused on relatively narrow domains of variables. It is apparent from the questions addressed by developmental psychopathologists that progress toward a process-level understanding of mental

disorders will require research designs and strategies that call for the simultaneous assessment of multiple domains of variables both within and outside of the developing person (Cicchetti & Dawson, 2002). Similarly, research in the area of resilience must follow these interdisciplinary multiple-levels-of-analysis perspectives (Cicchetti & Blender, 2004; Curtis & Cicchetti, 2003). In some instances, reference to variables measured in other domains is essential to clarify the role(s) of variables of interest for other questions; it is necessary to consider variables from other domains as competing explanations for postulated causal paths. To understand psychopathology fully, all levels of analysis must be examined and integrated. Each level both informs and constrains all other levels of analysis. Moreover, the influence of levels on one another is almost always bidirectional (Cicchetti & Cannon, 1999; Cicchetti & Tucker, 1994).

Because different levels of analysis constrain other levels, as scientists learn more about multiple levels of analysis, researchers conducting their work at each level will need to develop theories that are consistent across all levels. When disciplines function in isolation, they run the risk of creating theories that ultimately will be incorrect because vital information from other disciplines has either been ignored or is unknown. Just as is the case in systems neuroscience, it is critical that there be an integrative framework that incorporates all levels of analysis about complex systems in the development of psychopathology.

One of the major challenges confronting scientific progress involves establishing communication systems among disciplines. For example, despite tremendous technological advances in neuroimaging and molecular genetics, great knowledge gaps remain between scientists who possess competence with the technologies and methods of brain imaging and genetics and those who are comfortable with the complex issues inherent in the investigation of development and psychopathology. Consequently, the field has not yet made optimal use of the advances in technology that have taken place (Posner, Rothbart, Farah, & Bruer, 2001).

RESILIENCE

As stated previously, developmental psychopathologists are as interested in individuals at high risk for the development of pathology who do not manifest it over time as they are in individuals who develop an actual mental disorder (Cicchetti, 1993; Cicchetti & Garmezy, 1993; Cicchetti & Toth, 1991; Luthar, 2003; Luthar et al., 2000; Masten, 1989, 2001; Masten, Best, & Garmezy, 1990; Rutter, 1990; Sroufe & Rutter, 1984). Relatedly, developmental psychopathologists

also are committed to understanding pathways to competent adaptation despite exposure to conditions of adversity (Cicchetti & Rogosch, 1997; Egeland, Carlson, & Sroufe, 1993; Flores et al., 2005; Kim-Cohen, Moffitt, Caspi, & Taylor, 2004; Masten, 2001; Masten et al., 2004). In addition, developmental psychopathologists emphasize the need to understand the functioning of individuals who, after having diverged onto deviant developmental pathways, resume normal functioning and achieve adequate adaptation (Cicchetti & Rogosch, 1997; Masten et al., 1990).

Resilience has been operationalized as the individual's capacity for adapting successfully and functioning competently despite experiencing chronic adversity or following exposure to prolonged or severe trauma (Luthar et al., 2000; Masten et al., 1990). The roots of work on resilience can be traced back to prior research in diverse areas, including investigations of individuals with Schizophrenia and their offspring, studies of the effects of persistent poverty, and work on coping with acute and chronic stressors (Cicchetti & Garmezy, 1993). By uncovering the mechanisms and processes that lead to competent adaptation despite the presence of adversity, developmental psychopathologists have helped to enhance the understanding of both normal development and psychopathology. We concur with Rutter (1990, p. 210) that resilience does not exist statically in the "psychological chemistry of the moment." It is a dynamic process, and genetic, biological, and psychological processes exert a vital role in how individuals fare when they are exposed to adversity (Curtis & Cicchetti, 2003; Kim-Cohen et al., 2004).

Within this perspective, it is important that resilient functioning not be conceptualized as a static or traitlike condition, but as being in dynamic transaction with intra- and extraorganismic forces (Cicchetti, Rogosch, Lynch, & Holt, 1993; Egeland et al., 1993). Research on the processes leading to resilient outcomes offers great promise as an avenue for facilitating the development of prevention and intervention strategies (Cicchetti & Toth, 1992; Toth & Cicchetti, 1999). Through the examination of the proximal and distal processes and mechanisms that contribute to positive adaptation in situations that more typically eventuate in maladaptation, researchers and clinicians will be better prepared to devise ways of promoting competent outcomes in high-risk populations (Luthar & Cicchetti, 2000).

TRANSLATIONAL RESEARCH

In recent years, the National Institute of Mental Health (NIMH) has become greatly interested in fostering and supporting translational research in the behavioral and so-

cial sciences (Cicchetti & Toth, 2000, in press b). As funding decisions at the NIMH increasingly become tied to reducing the burden of mental illness and to the real-world application of research findings, investigators will need to devise and implement policy-relevant investigations. In a report of the National Advisory Mental Health Council on Behavioral Sciences (2000) entitled *Translating Behavioral Science into Action*, strategies for enhancing contributions of behavioral science to society more broadly are proposed. The report of the workgroup concludes, "At present too few researchers are attempting to bridge across basic, clinical, and services research, and not enough are working with colleagues in related allied disciplines to move research advances out of the laboratory and into clinical care, service delivery, and policymaking" (p. v). In this report, "translational research is defined as research designed to address how basic behavioral processes inform the diagnosis, prevention, treatment, and delivery of services for mental illness, and, conversely, how knowledge of mental illness increases our understanding of basic behavioral processes" (p. iii). This formulation of translational research is in direct accord with two of the key tenets of a developmental psychopathology perspective, namely, the reciprocal interplay between basic and applied research and between normal and atypical development (Cicchetti & Toth, 1991, in press a).

The parameters of developmental psychopathology lend themselves to fostering translational research that has implications for society, policymakers, and individuals with mental disorders and their families. The very subject matter of the field, which encompasses risk and resilience, prevention and intervention, the elucidation of precipitants of mental illness, the mediating and moderating processes that contribute to or mitigate against the emergence and maintenance of psychopathology, a multiple-levels-of-analysis approach, and the incorporation of principles of normal development into the conduct of empirical investigations, necessitates thinking clearly about the implications of the work and devising strategies that will remedy the problems being studied.

PREVENTION AND INTERVENTION

Now that we have examined some illustrative principles of a developmental psychopathology perspective and their relevance to investigating adaptation and psychopathology, we next discuss how the developmental psychopathology framework can similarly assist in the development and provision of prevention and intervention to individuals who are at high risk for or who have developed psychopathology.

Theory and research on basic developmental processes can and should inform prevention and intervention efforts to a greater extent than is the current norm. Clinical research on treatment and preventive strategies can provide unprecedented and essential insights translatable to the making of further theoretical advances (Cicchetti & Hinshaw, 2002; Cicchetti & Toth, 1999; Kellam & Rebok, 1992; Koretz, 1991).

For example, if the developmental course is altered as a result of the implementation of a randomized preventive intervention trial and the risk for negative outcomes is reduced, then prevention research has contributed to specifying the processes that are involved in the emergence of maladaptive developmental outcomes and psychopathology (Cicchetti & Rogosch, 1996; Coie et al., 1993; Hinshaw, 2002; Kellam & Rebok, 1992). Accordingly, preventive intervention research can be conceptualized as true experiments in modifying the course of development, thereby providing insights into the etiology and pathogenesis of disordered outcomes. The time has come to conduct randomized prevention trials that not only assess behavioral changes, but also ascertain whether abnormal neurobiological structures, functions, and organizations are modifiable or are refractory to intervention. There is growing evidence that successful intervention modifies not only maladaptive behavior, but also the cellular and physiological correlates of behavior (D. B. Kandel, 1998; E. R. Kandel 1979, 1999).

Prevention research is based on theoretical models of how risk conditions are related to adverse outcomes. As such, it posits processes that link the risk condition to the negative outcome (Institute of Medicine, 1994; Munoz, Mrazek, & Haggerty, 1996; Reiss & Price, 1996). Intervention efficacy may be enhanced by knowledge of developmental norms, appreciation of how a developmental level may vary within the same age group, sensitivity to the changing meaning that problems and disorders have at different developmental levels, attention to the effects of developmental transitions and reorganizations, and an understanding of the factors that are essential to incorporate into the design and implementation of preventive interventions (Cicchetti & Rogosch, 1999; Cicchetti & Toth, 1999; Coie et al., 1993; Institute of Medicine, 1994; Munoz et al., 1996; Noam, 1992; Reiss & Price, 1996; Toth & Cicchetti, 1999).

Inquiries regarding developmental theory and findings on basic developmental processes are all too often quite removed from both clinical practice and clinical research (Cicchetti & Toth, 1998; Kazdin, 1999). Despite rhetoric directed to the principle that developmental theory should inform active clinical intervention with children and ado-

lescents—and the converse contention that treatment research should inform relevant theory—the gap between these two endeavors is still broad. Indeed, in many ways, those who perform basic developmental research and promote developmental theory appear to constitute a different culture from those who pursue related prevention and intervention efforts. At the extremes, clinically oriented investigators and practitioners perceive basic academic developmental science as overly concerned with central tendencies and universal, developmental norms, to the exclusion of the rich variability and nonnormative behavior patterns that they confront on a daily basis. Conversely, theorists and academic scientists appear to construe much of the clinical endeavor as atheoretical and ungrounded in core scientific principles and theories (Cicchetti & Toth, 1991, 1998).

This state of affairs is particularly distressing given the advances that are being made in a host of basic behavioral and biomedical sciences and the urgent clinical needs of large numbers of children, adolescents, and families afflicted by mental and developmental disorders (U.S. Department of Health and Human Services, 1999). Because of the field's still nascent ideas as to the underlying mechanisms of most forms of psychopathology, the need for direct application of basic research advances to enhance clinical efforts can only be described as essential. Yet, despite the increasing call for translational research that can bridge basic and applied efforts, the barriers that exist regarding the application of such basic research advances to clinically relevant work are real (Institute of Medicine, 2000). It is essential that so-called basic investigators receive updated information about fundamental processes that are relevant to clinical disorders.

Another means of closing the schisms that exist between academic researchers and clinicians is to undertake interdisciplinary, collaborative preventive interventions that take into account multiple levels of influence, spanning genes to neighborhoods and individuals to social groups (Cicchetti & Dawson, 2002). Indeed, integrative, multidisciplinary efforts that bridge these different cultures can capitalize on unprecedented opportunities for fostering a mutual perspective. As stated earlier, a central tenet of developmental psychopathology is that the understanding of atypical development can inform the understanding of normal development, and vice versa, as long as consideration is given to contextual variables and developmental principles in the explanation of how development can go awry (Cicchetti & Cohen, 1995a, 1995b). We extend this assertion through our contention that methodologically rigorous prevention and intervention science can provide a unique

lens through which to discern the processes responsible for the development, maintenance, and alteration of both typical and atypical functional patterns (Cicchetti & Toth, 1992; Hinshaw, 2002; Kellam & Rebok, 1992).

There are several reasons prevention and intervention efforts can play an essential role in bridging the world of research and clinical work and in fostering theoretical advances. First, investigations of clinical populations may inform understanding of processes responsible for healthy and atypical development, but again, only so long as careful attention is directed to the underlying mechanisms responsible for pathological outcomes (Hinshaw, 2002). Second, and crucially, whereas much of the work in the field is, of necessity, naturalistic and correlational in nature, given ethical constraints on randomly assigning developing persons to key environmental or psychobiological conditions, the gold standard for clinical intervention and prevention research is the randomized clinical trial. The experimental nature of such investigations provides an unprecedented opportunity to make causal inferences in the field (Cook & Campbell, 1979; Kraemer, Wilson, Fairburn, & Agras, 2002). Although the types of independent variables manipulated in clinical or prevention trials may be several steps removed from crucial, underlying etiologic factors, given that such trials are primarily concerned with the practical, clinical goals of alleviating suffering and promoting competence rather than isolating primary causal variables, careful research design and assiduous measurement of ancillary, process variables through which intervention effects may occur can shed unexpected light on theory-driven mechanisms underlying healthy and pathological development (Hinshaw, 2002; Kraemer et al., 2002).

Finally, as research on the contributors to resilient functioning has evolved, several scientists have suggested, based on knowledge of the extant empirical literature, how to develop preventive interventions aimed at promoting competent adaptation in a variety of high-risk groups (see, e.g., Cowen, 1991, 1994; Luthar & Cicchetti, 2000; Yoshikawa, 1994). A number of recommendations for competence-promoting interventions have been made, including the following: (1) They must be firmly grounded in theory and research; (2) efforts should be directed not only toward reducing maladaptation and psychopathology but also at promoting competence; (3) programs must capitalize on the particular resources and strengths of individual children in specific populations; (4) there should be a focus on vulnerability and protective processes that operate across multiple levels of influence; and (5) they should be guided by a strong developmental-contextual theoretical perspective (Luthar & Cicchetti, 2000). In addition, pre-

vention and intervention should be designed to elucidate the mediators and moderators of resilient outcomes and recovery to adaptive functions.

CONCLUSION

In a relatively brief period, developmental psychopathologists have contributed significantly to our understanding of risk, disorder, and adaptation across the life course. Much of the momentum of developmental psychopathology has stemmed from an openness to preexisting knowledge in combination with a willingness to question established beliefs, thereby continuing to promote disciplinary growth. The integration of concepts and methods derived from areas of endeavor that are too often isolated from each other has resulted in knowledge advances that might have been missed in the absence of cross-disciplinary dialogue.

Numerous challenges lie ahead, and we must have the courage to continue to critically examine the implicit as well as the explicit conceptual and scientific assumptions that exist in the field of developmental psychopathology to sustain our momentum and to foster new advances (Cicchetti & Richters, 1997). Future investigations must strive to attain enhanced fidelity between the elegance and complexity of the theoretical models and definitional parameters inherent to a developmental psychopathology perspective and the design, measurement, and data analytic strategies employed in our investigations (Granic & Hollenstein, 2003; Richters, 1997). Moreover, we believe that the continuation and elaboration of the mutually enriching interchanges that have occurred within and across disciplines interested in normal and abnormal development will enhance not only the science of developmental psychopathology, but also the benefits to be derived for society as a whole.

The impressive array of findings in the more recent psychological developmental literature mentioned earlier, in concert with the concomitant progress made in the neurosciences, genetics, and related disciplines, has led to increasing acknowledgment of the need to conduct collaborative, multidisciplinary, multidomain studies on normal, high-risk, and psychopathological populations. It has now become more widely accepted that research into pathological conditions must proceed hand-in-hand with so-called basic research into human functioning. As progress in ontogenetic approaches to various subdisciplines of developmental psychopathology continues, the common theoretical and empirical threads running through this work will coalesce to establish a foundation on which an increasingly

sophisticated developmental psychopathology discipline can grow. The power embodied by cross-disciplinary collaborations that utilize multiple-levels-of-analysis methodologies promises to significantly strengthen our capacity to decrease the burden of mental illness for society.

Closing Comments	37
REFERENCES	37

Dramatic advances have been noted in the past 15 years in our understanding of childhood psychopathology. With the emergence of more tightly defined nosologic and diagnostic systems (e.g., *Diagnostic and Statistical Manual of Mental Disorders III*, *DSM-III-R*, and *DSM-IV*, American Psychiatric Association, 1980, 1987, 1994), we have seen the advent of large epidemiologic studies focused on describing risk factors and the prevalence of child psychopathology (e.g., see Costello et al., 1996; Flisher et al., 2000; Friedman, Katz-Leavy, Manderscheid, & Sondheimer, 1998; Goodman et al., 1998; Huffman, Mehlinger, & Kerivan, 2000; Shaffer et al., 1996), with most of these studies documenting overall ratings of moderate to severely impairing forms of psychopathology ranging from 3% to 22%. Although these widely diverging rates appear to cast significant doubt on how well our nosologic systems are actually working, most investigators in the field have concluded that these variations in rates are due principally to differences in methods in combining and weighting data from different sources and to variations in the level of impairment required before something should be deemed a disorder (Boyle et al., 1996; Regier et al., 1998).

Thus, the field has largely converged around similar conclusions supporting the descriptive manifestations of various forms of childhood psychopathology, as well as the importance of requirements of impairment, in order for the formal diagnosis of a mental disorder to be made. Likewise, the field has largely agreed that rates will vary as a function of the degree of impairment required for "caseness," and that these distinctions and determinations are largely set by policy and service availability considerations, rather than actual differences in children from sample to sample or any fundamental disagreements about the symptoms of psychopathology (Shaffer et al., 1996).

Longitudinal studies have also been essential, in that they have demonstrated both that many forms of psychopathology persist over childhood into adulthood, and that in many instances, psychopathology is often not stable; that is, many children with apparently severe conditions may no longer meet such criteria at later age points, just as presumably healthy children may develop significant mental health problems at later ages (Bennett et al., 1999; Bennett, Lipman, Racine, & Offord, 1998; Bennett & Offord, 2001; Loeber,

Stouthamer-Loeber, & White, 1999). These studies have been exceptionally important, because they serve as a two-edged reminder that (1) these conditions can have severe and prolonged impact many years later and hence need to be taken seriously; that is, they are not “just a stage”; and (2) the initial diagnoses of at least some forms of mental disorder or psychopathology in children and adolescents should be viewed cautiously, to the extent that children, their brains, and their larger environments can change, so that possibilities for amelioration and perhaps even “cure” should not be foreclosed.

The development of more reliable diagnostic systems and measures has also spawned a great deal of research into effective psychosocial and psychopharmacologic intervention methods for persons suffering from these conditions. Beginning in the early and mid-1990s, a host of large-scale prevention and intervention trials were begun, with many now successfully completed. Both in children and adults, these many empirical studies generated important findings about “what works” for the various mental disorders that have been studied; further, they have led to a call for implementing evidence-based practices (EBPs) in the real world (Office of the Surgeon General, 1999). This outcome, arguably, is one of the distal impacts of our embracing and implementing a more descriptive, atheoretical, and easily operationalized diagnostic system.

ALL IS NOT AS IT SEEMS: PROBLEMS BELOW THE SURFACE

Despite these advances in diagnosis and treatment, a number of particularly thorny difficulties have remained incompletely addressed, adding an air of disquietude to the otherwise seemingly certain sense of progress. For example, the current diagnostic systems often do not exactly fit many real-world patients, and patients often have symptom constellations that cross multiple diagnostic categories but rest securely in none. Many times, such persons may show evidence of substantial impairment, suggesting that they have a clear clinical need for some type of intervention, but our classificatory system somehow misses them (Angold, Costello, Farmer, Burns, & Erkanli, 1999). Other patients, perhaps the majority, who *do* meet criteria for a *DSM* disorder actually have more than one, often two or three, regardless of whether they are found in epidemiologic studies or clinical settings. Unfortunately, the many combinatory patterns of diagnostic profiles undermine the credibility and swamp the usefulness of the classification system.

Imagine if we had a system for classifying common respiratory illnesses, with over 100 of these illnesses presumably relatively common, and that most people with such illnesses usually had two or more. If we were to try to study such respiratory illnesses, studying them in pure form would omit most patients with bona fide illness, and attempting to study them in their more complex presentation would at some point surely overtax our ability to group, classify, and make sense of what we think we see. Or consider the physician who, after taking a careful history, learns of a patient’s 1-week history of watery eyes, cough, loss of appetite and nausea, stomach cramping and diarrhea, general fatigue, and sore joints and muscles. The physician then examines the patient and finds a mildly elevated temperature (101 degrees), somewhat dry mucous membranes in the nose and mouth, and hyperactive bowel sounds, but no evidence of abdominal tenderness or swelling, and a mildly elevated pulse with a low normal blood pressure. Rather than assume the patient has 12 to 13 different syndromes (based on the total count of the signs and symptoms described, most physicians might make a *single diagnosis* [flu], perhaps complicated by slight dehydration, especially if this occurs during a particular time of the year). Knowing any one of the symptoms thoroughly would not be as informative as understanding the overall pattern and underlying illness process. Such a global understanding of the patterns and processes is especially important if one wishes to make meaningful predictions about the course of this constellation of symptoms, or to make sensible recommendations about what should be done (bed rest, hydration, light and nutritious meals, and time). Interestingly, the sore joints presenting without the other symptoms might be suggestive of an altogether different process (previous injury, overexercise, arthritis, or even lupus).

It is in our understanding of the underlying illness process, the overall patterning of the signs and symptoms, and the history and context of the symptoms that enables distinctions to be made between a flu syndrome and an exercise injury. But, as is the case in childhood mental health problems, what should we do if our major symptom profile descriptions and common categories result in 10 or more major groups (e.g., anxiety disorders, Obsessive Compulsive Disorder, Major Depression, Bipolar Disorder, Attention-Deficit/Hyperactivity Disorder, Conduct Disorder, Oppositional Defiant Disorder, Tourette’s syndrome, Autism, other developmental disorders, and substance use disorders), any of which might commonly co-occur, generating 2^{10} (1,024) possible different patterns, particularly when issues of history, context, and contributing/exacerbating factors are

generally not considered as a part of the taxonomic approach? How can we be sure that we are forming sensible clusters of symptom patterns that seem to hang together?

Concerns about our classification approaches are not limited to the child psychopathology field alone. Reservations have been raised about the overly descriptive nature of the various versions of *DSM* that do not take into account the effects of various etiologic and contextual factors readily discerned by experienced clinicians. Instead, currently observable behaviors are highlighted, and these taxonomic models of psychopathology generally do not consider the possibility that “psychopathology” in some instances may reflect the attempts of the organism to adapt to the broader environmental context. Moreover, these concepts of psychopathology assume a relatively stable deficit *within the individual* (American Psychiatric Association, 1994). Perhaps most important, these diagnostic approaches have been appropriately criticized on the grounds of both over- and underinclusiveness, the potential for misdiagnosis and misuse, and credibility (Richters & Cicchetti, 1993; Wakefield, 1992a, 1992b). Compounding all of these difficulties is the fact that revisions often have occurred before sufficient research documenting the usefulness and validity of the categories outlined in previous versions had been conducted.

The purposes of this chapter are to (1) briefly review the purposes of diagnostic and classification systems in general; (2) review the merits and constraints of the current *DSM* classification system that relies on a descriptive symptom-based approach, examining the benefits and hazards afforded by these classification and diagnostic strategies; (3) outline alternative approaches that take fuller advantage of other forms of clinical data; and (4) make recommendations for the next generation of classification systems, both in terms of the nature of these systems as well as the programs of research that will be needed to expand our knowledge of psychopathology and mental disorders.

PURPOSES OF CLASSIFICATION AND DIAGNOSIS

Why classify? And why is classification important in science? The simple answer is that classification renders induction possible. For science to occur, there must be groupings of phenomena, and these groupings must be structured in such a way as to render reliable the generalizations established in connection with observations (Pratt & Foucault, 1977). In fact, it can be argued that there can be no science without classification (Wallace, 1994). Yet, selection and construction of nosologic systems involves decisions. Such

systems do not arise naturally but are imposed on nature through decisions of inclusion and exclusion. Foucault (1970) noted that taxonomies are not part of any effort to “look harder and more closely” at things but, rather, “to restrict deliberately the area of its experience”—that is, to reduce the observer’s awareness by censoring out large ranges of a given object’s features. The implication of this is that taxonomies are not objective legitimizations of the “true nature” or division of things, because any nosologic system presupposes certain human-made decisions and methodologies (Dupre, 1993; Sadler, Wiggins, & Schwartz, 1994).

A brief look at the history of biological classification systems offers instructive lessons in the prevailing ideas about science and its relationship to objects of study. Numerical taxonomy arose in part from the work of the French natural historian Adanson, who, in 1763, recommended that any classification of items should be based on overall similarity, developed by attention to describing the external features of the objects in question. The outward visible form was the defining aspect of any description and was thought to constitute a supraordinate connection across disparate phenomena.

In the post-Newtonian period, the basis of taxonomy changed. The idea arose that things had internal structures, not just outwardly observable characteristics, and that these structures were not visible but invisible, internalized *essences*. Drawing in part on the thinking of Aristotle and Plato, essentialism was adopted by biologists in the seventeenth and eighteenth centuries and applied to the concept of species. Species’ essence became a causal mechanism that operated on any given member of a species and constituted the essence of what that species was. With the advent of Cuvier’s (1835) work on comparative anatomy, living things were seen as dynamic systems, and analysis of systems required understanding of the function of each part. Cuvier referred to the idea of functional organization in terms of “archetypes” or plans, according to which the organisms were constructed. Only after Darwin did a more thoroughgoing theory of classification based on cladistics make understanding of evolutionary relationships possible (Pratt & Foucault, 1977). The concept of an archetype became isomorphic with the concept of common ancestry, and groupings according to evolutionary relationships became possible. It is interesting to note that classification systems in psychiatry have not invoked the explanatory power that evolutionary theory enables, yet it may now be possible to construct a psychiatric classification system that embodies the workings of evolution (e.g., see Jensen et al., 1997; Leckman & Mayes, 1998; Marks & Nesse, 1994; Nettle, 2004).

The transformation of taxonomies from outwardly visible descriptions, to essentialist notions of invisible struc-

tures, to evolutionary adaptive relations implies that the kinds of questions about objects being classified need modification. It is no longer appropriate to simply ask of an object, What is the natural kind to which it belongs? (an *essentialist* question). Rather, we should ask, What is the goal underlying the intent to classify the object? (Dupre, 1993; Popper, 1994).

In this context, it is instructive to note the purposes to which classification systems have been put. Feinstein (1972) noted that classification serves three principal functions: denomination (assigning a common name to a group of phenomena), qualification (enhancing the usefulness of the name or category by adding pertinent descriptive features such as characteristic signs, symptoms, age of onset), and prediction (probabilistic statements about the clinical course, outcome, response to treatment, etc.). The typical standard that has promoted the longevity of most classification systems is their *usefulness*. However, any system may have multiple purposes, and these purposes do not necessarily converge. Thus, a given classification system designed to serve scientific purposes might be purposively narrow, avoiding false positives and overinclusiveness, with the goal of determining common etiologies and an array of specific treatments. On the other hand, such a system may do a disservice to persons who are suffering from a similar symptom profile, yet who could be excluded from treatment or services if they do not fit the narrower profile more appropriate for certain research purposes. Thus, a system designed to identify persons in need of public services may be quite broad (witness the broad categories used in the Department of Education's determination of a child's eligibility for special education services), even though heterogeneous etiologies may be embedded in the descriptive profile (Eisenberg, 1995).

BENEFITS OF PSYCHIATRIC DIAGNOSIS

Increased Diagnostic Reliability

The more modern versions of the *DSM*, from *DSM-III* on, were developed principally to first solve the problem of unreliability in diagnoses. As a consequence, clearly operationalized lists of symptom criteria were developed for disorders that psychiatrists and other mental health professionals found to characterize similar clusters of patients seen in practice. Prior to that point, a number of studies had demonstrated that psychiatric diagnoses among different experts rarely achieved agreement greater than 20% to 30%. Given clinicians' difficulties in coming to agreement on the nature of the difficulties of a given patient, the re-

cent *DSM* systems (from *DSM-III* forward) were meant to offer a clean break from the theory-burdened, nonempirical diagnostic practices of the past. At the very least, these systems were meant to be reliable, with the goal that over time, scientists and classificationists would work toward more etiologically based systems. The history of knowledge development in the medical sciences has often been characterized as moving from descriptive models of understanding illnesses and syndromes to a better knowledge of underlying pathophysiology (though this level of understanding has yet to be achieved in many areas of clinical medicine; Eisenberg, 1995). According to this view, just as in other areas of medicine, a symptomatic stage of classification is a necessary precursor to the development of empirically demonstrated etiologic theories (Sadler, Wiggins, & Schwartz, 1994).

Increased Scientific Communication and Accelerated Scientific Discovery

With the goal of eventually identifying empirically based etiologic underpinnings of mental disorders, recent *DSM* developers made an explicit attempt to move beyond expert consensus that characterized earlier *DSM* versions and to rely instead on empirical documentation via extensive field trials and reanalyses of existing data sets. Particularly in *DSM-IV*, such data were used to determine the inclusion/exclusion of specific diagnostic criteria, diagnostic thresholds, and required levels of impairment (e.g., see Lahey et al., 1994). In addition, higher thresholds were established for making revisions; greater attention was paid to the needs of users in the fields of education, research, and clinical practice; and increased breadth and quality of the field's participation was sought in developing the revision by establishing multiple workgroups, each with 50 to 100 advisors and participants. Other attempts to move the *DSM* classification system forward included the abandonment of hierarchical assumptions (beginning first with *DSM-III-R*) and the explicit attempt to be atheoretical by avoiding clinical or etiologic inferences, relying instead on readily described, easily observed (or reported) behavioral, cognitive, and emotional symptoms (Frances, Pincus, Widiger, Davis, & First, 1994)—as if such an approach were atheoretical!

Nonetheless, the advent of more scientifically replicable diagnostic systems and assessment measures also led to new activities not previously seen in the children's mental health field: large-scale federally sponsored clinical trials testing various interventions with children or adolescents meeting specific diagnostic criteria. These include the National

Institute of Mental Health Multi-Modal Treatment Study of ADHD (MTA Cooperative Group, 1999), studies of the various Research Units on Pediatric Psychopharmacology (McDougle et al., 2002; Research Units on Pediatric Psychopharmacology Anxiety Study Group, 2002), the Treatment of Adolescent Depression Study Team (2004), and a bevy of industry-sponsored studies (see Pappadopulos, Guelzow, Wong, Ortega, & Jensen, 2004, for a review). Paralleling these pharmacologic studies are many studies testing the efficacy of specific forms of psychotherapy for various conditions, ranging from Major Depression (Brent et al., 1997; Clarke et al., 2002) to anxiety disorders (Silverman, Kurtines, Ginsburg, Weems, Rabian, et al., 1999), OCD (Franklin, Foa, & March, 2003), Conduct Disorder (Kazdin & Whitley, 2003), and Oppositional Defiant Disorder (Hood & Eyberg, 2003; Webster-Stratton, Reid, & Hammond, 2004).

These many empirical studies have increasingly led to a call for the need to implement EBPs, with the a priori assumption that unless proven otherwise, childhood conditions when manifest should be treated by one of the EBPs, with the concomitant implication that funding of practices that are not evidence based be withheld. Thus, one might argue that for good or ill, the distal end of this process of unification of the scientific field in favor of a particular nosology and diagnostic system has led to changes beyond scientific arenas into societal practices, including changes in policies about how taxpayer dollars are spent.

CONSTRAINTS OF CURRENT SYSTEMS

Increased Reliability, but at What Cost?

Although the recent diagnostic systems have achieved reliability when tested in formal research settings, concerns have been raised that excessive emphasis on test-retest and interrater reliability runs the risk of generating unicausal or theoretically impoverished models of psychopathology, simply because classes of information that are more important yet more difficult to operationalize and assess reliably tend to be eliminated from scientific consideration. For example, symptom-only descriptive approaches may fail to take into account the effects of various etiologic factors, experience, and developmental history on individuals' current functioning, as well as other contextual factors more readily discerned by experienced clinicians (Perry, Cooper, & Michels, 1987; Rutter & Shaffer, 1980; Vaillant, 1984). Interviewing patients for reliably reported signs and symptoms of disorders necessarily omits por-

tions of clinical reality, such as information pertaining to contextual, interactional, and/or historical factors that may have contributed to the development of the condition. Observable behaviors are highlighted, as if divorced from meaning and motivation, and inconvenient or difficult classes of information are eliminated or, at best, truncated (Trickett, 1996; Wallace, 1994). These taxonomic models of psychopathology generally do not consider the possibility that psychopathology in some instances may actually reflect the attempts of the organism to adapt to the broader environmental context. Failing to take such issues into consideration could redirect clinicians' (or society's) intervention efforts to what would be principally seen as "helping disturbed individuals" rather than addressing problematic environments.

Categorical Distinctions versus Dimensional Characteristics?

A major conceptual consideration underpinning determination of mental disorder depends on whether one considers that the underlying construct is a true category, qualitatively different from other disordered as well as normal states, or whether in fact caseness simply reflects difficulties in functioning at the extreme end of a continuum. Although most psychiatric disorders, child and adult alike, can be shown to be quantitatively different from "normal" states, such differences do not necessarily reflect qualitative differences. Large differences between two groups on a number of markers do not necessarily make them different *in kind*, any more than concluding that tall persons and short persons are qualitatively different, or that there appears to be a "tall syndrome"—weighing a lot, having long fingers, and wearing big hats. Finding both quantitative and qualitative differences among persons with and without a particular definition of mental disorder *might* constitute a partial argument in support of that particular definition of mental disorder, but two different kinds, even when such can be identified, may have the same final common pathway, in terms of the observable phenomenology, just as two cases of the same kind may have very different outcomes, making the sole use of qualitative distinctions as an indicator of mental disorder problematic (Andreasen & Glick, 1988). To return to the model of height, it is not being short or tall alone that makes someone "pathologically" tall versus normally tall. It may be other associated factors, such as the presence of a disturbance in the endocrine system or bone metabolism (Eisenberg, 1995).

If one asks whether the current *DSM* "carve[s] nature at its joints," the research literature principally answers in the

negative. For example, in a study of the diagnostic criteria for depression using a sample of monozygotic and dizygotic twins, Kendler and Gardner (1998) examined the diagnostic criteria for number of symptoms, severity, and duration, finding that number of symptoms and severity (but not duration) predicted increased likelihood of subsequent episodes in the index case and the twin. However, there was no natural cut point at four symptoms: Even persons with fewer than five symptoms, as well as having less severe symptoms (below the diagnostic threshold) were at greater risk for subsequent episodes of depression, both in the index case and the twin. These findings suggested that even subthreshold depressive symptoms reveal the same underlying diathesis. In addition, no support was found for the requirement of 2 weeks' duration or some threshold of clinical severity. Thus, Major Depressive Disorder appeared to be a diagnostic convention imposed on a continuum of depressive symptoms of varying severity, impairment, and duration. Similar results have been found in the area of genetic studies of ADHD, where heritability analyses of full-syndrome versus subthreshold symptom states suggested that the condition likely reflected a continuum versus an all-or-none, present-absent psychopathological state (Levy, Hay, McStephen, Wood, & Waldman, 1997; Rasmussen et al., 2002), and analyses of the age-of-onset criterion fail to make important distinctions in course, outcome, and response to treatment (Barkley & Biederman, 1997).

At present, there is little evidence to indicate *natural* dichotomies between cases and noncases in most of our categories of child and adolescent psychopathology, perhaps with Autism and childhood-onset Schizophrenia being two exceptions. This has led many scholars to advocate *dimensional* approaches to the definition and assessment of child and adolescent psychopathology rather than *categorical* diagnostic approaches. Yet, both clinical practice and policymaking often require dichotomous decisions about the mental health of youths. Clinicians must make dichotomous decisions to treat or withhold treatment on a daily basis; researchers seek to classify the phenotypes of psychopathology to conduct genetic studies; and policymakers often engage in activities such as counting the number of youths who need mental health services but have not received them. Thus, there is a tension between the need for categorical definitions of mental disorder for many important purposes and the lack of evidence to support such dichotomous categorizations.

Conceptual Problems with Mental Disorder Construct

These recent strategies to address some of the difficulties of the *DSM* taxonomies may have been useful and appear to

have led to research advances and attempts to apply research findings to real-world practices. However, no nosologic approach, whether *DSM*, *International Classification of Diseases 10*, or various dimensional systems for measuring psychopathology (e.g., see Achenbach, 1993, 1995) has adequately addressed the thorny construct of "mental disorder." Frances (1994), the leader of the *DSM-IV* effort, stated that "there could not be any worse term than 'mental disorder,'" yet he noted that other terms were even more unsatisfactory. Because the *DSMs* are meant to be a "way station" en route to more valid approaches, he cautioned investigators and clinicians not to reify the diagnoses and taxonomic system. Even the term "mental disorder" implies a mind-body dichotomy that is outmoded and not embraced by most present-day basic neuroscientists and developmental neurobiologists (Black, Sirevaag, Wallace, Savin, & Greenough, 1989; Greenough & Black, 1992; Nelson & Bloom, 1997; Strumwasser, 1994). Most likely, there is no hard and fast line between so-called biological and sociocultural factors in health, normality, and disease (Eisenberg, 1995), and few (if any) of the so-called mental disorders can be conceptualized purely at a molar or individual organismic level. Thus, if one were to simplify our understanding of tuberculosis as a biologic infectious disease in some individuals but not others, such a conceptual framework might lead one to a very different set of interventions (pharmacotherapeutics) than if one were to approach the problem from a public health perspective, guided by the knowledge that many persons are exposed to the tubercle bacillus but never develop active illness, unless accompanied by socioeconomic and environmental factors such as poverty, crowding, and other, as yet unidentified factors. Thus, for many mental health problems, it takes understanding of the person *and* his or her current environment to understand the disorder or disease. This applies not only to mental disorders, but also to many other complex illnesses, such as hypertension, diabetes, heart disease, immune diseases, and cancer (Margolis, 1994).

What complicates our definition of mental disorder is that our understanding of individuals' behavioral and emotional symptoms often depends on and is constituted by the person's culture, psychosocial and biologic history, and environment. Such complexity appears to fly in the face of traditional approaches to disease and disorder classification. For example, Sydenham characterized disease this way:

Nature, in the production of disease, is uniform and consistent; so much so, that for the same disease in different persons the symptoms are for the most part the same; and the self-same phenomena that you would observe in the sickness

of a Socrates you would observe in the sickness of a simpleton. (quoted in Wiggins & Schwartz, 1994)

This principle may be somewhat true of many aspects of diseases such as pneumococcal pneumonia; it may be less applicable to diseases of the mind and brain. For example, cultural factors play an important role in determining when a symptom is a symptom, what constitutes impairment, and which cases need treatment. Rogler (1993) noted that a fine-grained analysis of psychotic symptoms with highly structured diagnostic instruments is difficult to make without knowledge of the culture's social values and traditions.

Even when question items are appropriately translated, the language and culture may use constructs that do not map neatly onto the *DSM*. For example, Manson (1995) noted that one item from the Diagnostic Interview Schedule that combined guilt, shame, and sinfulness required three different questions in the Hopi language to avoid confounding different items and meanings. Rogler notes that the configuring of symptoms into disorders may require changes from culture to culture, yet few studies have taken these issues fully into account. By way of exception, Canino et al. (1987), in implementing an epidemiologic survey of Puerto Rico, not only conducted tests to ascertain the reliability and validity of the diagnostic instruments, but added new items as needed and changed algorithms for various disorders in Puerto Rico. As a consequence of these changes, they found 66% lower disorder rates of Obsessive-Compulsive Disorder versus the unadjusted diagnostic algorithms. In contrast, dysthymia was 60% higher (Rogler, 1993) when adjusting for cultural factors.

Kleinman (1977) noted that it is fallacious to assume that mental illness is an "entity, a thing to be discovered in pure form by stripping away the layers of cultural camouflage. . . . There can be no stripping away of layers of cultural accretion in order to isolate a culture-free entity." The differential impact of disease processes on the brain (versus other bodily organs) is due in part to the brain's high degree of evolved plasticity, malleable throughout life by virtue of learning and sculpting processes occurring at the level of individual dendritic spines, cells, synapses, and neuronal circuits (Greenough & Black, 1992; Nelson & Bloom, 1997). Culture and context structure many, if not all, aspects of mental illness: A given person's subjective experience is culturally shaped, as are the meanings he or she ascribes to symptoms, as is the phenomenon of having a mental disorder itself, and ultimately, even the classification systems by which different groups of persons are classified (or diagnosed).

Is the Disorder within the Individual?

Viewed through the lens of developmental psychopathology, one must ask whether a given disorder need be conceptualized as "within the person" or even "mental" per se. Indeed, some anthropologists have noted that the interiorized sense of self—the psychological human versus his or her society and environment—is a relatively recent phenomenon, mostly of Western and industrialized society. Western-raised ethnologists who have studied and lived in communal societies have described their own loss of the sense of the individual self in these societies (Shweder & Bourne, 1991; Wallace, 1994). With a greater focus on the larger social context, it is quite plausible to suggest that families, communities, or society at large are "dysfunctional" (e.g., Fromm, 1955). The notion of a disorder being only *in the person* belies an individualistic metaphysic: namely, that minds reside in brains, but that minds, and subsequently mental disorders, do not reside in the social world. This is an implausible and logically unsustainable tenet (Sadler & Hulgus, 1994; Shweder & Bourne, 1991; Trickett, 1996). Instead, minds, as well as all mental disorders, reside in communities, neighborhoods, and families, facts that have great significance for and guide the activities of most clinicians.

If one conceptualizes the disorder as something that does not necessarily lie inside the skin of an individual, but may in some instances reside in the transactions between the individual and the environment, an entirely different set of measurement and assessment demands are imposed on the investigator. Meaningful outcomes can no longer be captured by an exclusive focus on signs and symptoms. Instead, adaptive functioning, the nature of the surrounding environment, and the relationship between organism and environment become critical areas for assessment, perhaps even central for understanding of a given disorder. In fact, it seems plausible that understanding of individual organismic functioning may be more explanatory and more fully addressable in terms of prediction *if* the larger context is assessed. The study of simple descriptive phenomena characterizing a given individual thus gives way to a relational understanding of the processes occurring between the individual and his or her environment.

To employ two simple illustrations: The study of the ebb and flow of the tides, though interesting and describable in great detail, will remain poorly understood if one fails to appreciate the relationship between the tides and the respective positions of the earth and the moon. Similarly, young infants' social-emotional behaviors, though interest-

ing descriptively, become more understandable when the child's affective state is understood as a function of the relationship with and proximity to the child's attachment figure. Once the functional processes and adaptive tasks that are facilitated by the child's proximity to and relationship with the caregiving parent are understood, better prediction of the child's affective state becomes possible, and new hypotheses follow from this fuller appreciation. This example illustrates the essential criterion whereby any new model can be judged: whether the new model offers increased ability to generate more accurate predictions about current and future behavior.

Thus, understanding the broad range of children's adaptive outcomes as a function of their environments is necessary to fully appreciate the terms "functioning," "functional processes," and "outcomes." Hoagwood, Jensen, Petti, and Burns (1996) have outlined a conceptual model (the SFCES model, denoting "symptoms," "functioning," "consumer-oriented," "environmental," and "systems/services") to guide the assessment of children within their environments across a range of outcomes. According to the SFCES model, symptomatic and diagnostic variables constitute an insufficient basis to characterize children's mental health outcomes. Adequate understanding becomes possible only to the extent that cognitive and social functioning; peer and family relationships; the nature of the child's school, neighborhood, and home environments; and cultural and societal contexts are also assessed and understood. Fuller understanding is realizable when these variables are characterized not just cross-sectionally but as a series of embedded, evolving, and dynamic transactions between the child, parents, family, neighborhood, school, and larger societal and cultural contexts *over time* (Boyce et al., 1998). Likewise, measurement of *processes* and reciprocal transactions between the organism and his or her environment and the potential adaptive (versus maladaptive) nature of the child's symptoms with respect to his or her environment is central to the understanding of mental disorders. Once understood, some such disorders might be better characterized as behavioral, emotional, transactional, or environmental, rather than as simply mental.

Can the *Diagnostic and Statistical Manual* (or Any Classification System) Be Atheoretical?

Sadler, Wiggins, and Schwartz (1994) have argued cogently that no diagnostic system can be truly atheoretical, because all observational statements are influenced by theoretical presuppositions. Likewise, this century's most re-

spected philosophers of science have suggested that it is impossible for any basic natural science, much less the clinical sciences, to be "value free" (Popper, 1994; Wallace, 1994). Any classificatory system is heavily influenced by the values, aims, and theories of the classifiers (Frances et al., 1994; Sadler, Wiggins, & Schwartz, 1994). The current *DSM* and other *DSM*-like approaches, by virtue of operationalizing criteria based on the presence of observable or reportable symptoms of individuals, by default imply that some kinds of clinical data are nosologically irrelevant. Consequently, Sadler and Hulus (1994) argue that because the current *DSM* systems do not always fully account for and specify the relevance of interactional data, they fit the needs of a biologic psychiatry much better than family-interactional, sociologic, developmental, or life history models of disorder. Frances and colleagues explicitly acknowledge this limitation, noting that although *DSM-IV* "attempts" to be atheoretical, no frame of reference can be without theory, and they suggest that *DSM*'s descriptive approach could possibly be more useful within behavioral and biologic orientations. On the other hand, although *DSM-IV* does not preclude other axes that might incorporate such data, integration of these perspectives into the *DSM* system is not likely to occur in the near future, in part because of the conceptual and methodological complexities that such an expansion of the classification system would entail.

Definitional Problems with Core Clinical Constructs

Upon close inspection, many terms in the *DSM* presuppose clinical determinations based on subjective judgments and norms within a given societal context. As a result, some experts have concluded that the presence of the diagnostic criteria alone are insufficient grounds for determining "when a case is a case" (Boyle et al., 1996). Many terms that are taken for granted (e.g., disorder, disturbance, failure, dysfunction, distortion, subaverage, deficit) are heavily value laden, subject to varying interpretations and idiosyncratic clinical practices. Further, the clinical norms on which such terms are based are subject to shifting values and changing societal inputs over time (Margolis, 1994). Remarkably, even core clinical constructs, such as "clinically significant impairment," are tautological (Fulford, 1994); that is, "clinically significant impairment" is the type of impairment that an experienced clinician recognizes and feels is severe enough to warrant treatment! Unless logically disentangled and recognized for what they

are, such tautologies can masquerade as, or even interfere with, the accumulation of knowledge.

Even when one determines the presence or absence of symptoms using the most rigorous methods, such as face-to-face diagnostic interviews, variations in mental disorder definitions are marked, based on ancillary determinations that are not necessarily part of the *DSM* criteria. And these variations affect mental health service need and use. For example, Angold et al. (1999) examined the impact of various definitions of *impairment* on rates of serious emotional disturbance, after first requiring that all children considered met all *DSM* symptomatic criteria. Using five different definitions of impairment in their study, Angold and colleagues compared children with neither impairment nor a diagnosis, those with no full-blown disorder but with impairment, those with disorder but no impairment, and those with both disorder and impairment. Even among those who met both symptom and more stringent impairment criteria, only 59% reported “need for services,” and fewer still (19%) of those meeting diagnostic criteria with levels of impairment as specified within the *DSM* criteria reported any need for services. Even with the most stringent impairment criteria, 66% of those with a defined serious emotional disturbance were not being served.

ALTERNATIVE APPROACHES

Given these problems, many authors have explored alternative approaches to conceptualizing mental health and illness. We describe some of the leading candidates below.

Harmful Dysfunction

Wakefield (1992a, 1992b) has noted that the philosophical underpinnings of the *DSM*'s accounts of disorder are structurally flawed and has argued that other accounts, such as “harmful dysfunction,” better describe a valid, conceptually sound construct of disorder that has the dual requirements of some sort of biologic dysfunction and cultural and contextual appraisal (see Kirk & Hsieh, 2004; Wakefield, Pottick, & Kirk, 2002) of impairment (“harm”) to warrant the determination of “true” mental disorder status. Both components (harm *and* dysfunction) must be addressed to identify a mental disorder. This approach appears promising, but it is still problematic to the extent that, for most mental disorders, it has not been possible to identify a biologic dysfunction within individuals, even in those with severely impairing conditions where evidence for genetic factors is indisputable (e.g., Autism). In addition, the defi-

nition suffers from the tautological definition of dysfunction as a “biologic system not behaving as it was designed to do” (from an evolutionary perspective), and such definitions invoke anachronistic notions of some hard and fast lines between so-called biologic and sociocultural factors (Nelson & Bloom, 1997; Wallace, 1994).

The similarity between Wakefield's concept of an “internal mechanism gone awry” and the pre-Darwinian (Cuvier, 1835) notion of the function of parts is notable. The same problems that applied to those earlier conceptualizations of classification may apply here. Nonetheless, in the same way that a more complete theory of classification became possible after the theory of evolution was enunciated, a dysfunction of a natural process cannot be understood outside of the context (the “ancestral environment of evolutionary adaptedness”) within which the process evolved. Thus, some presumed biologic dysfunctions are more readily conceptualized as the displacement of an organism from its original ecological niche, but these niches may be unknown to us at present (for additional discussion, see Bjorklund & Pellegrini, 2000; Jensen et al., 1997).

Empirical Taxonomic Approaches

One solution has been to dispense with the current diagnostic classification systems, such as *DSM-IV*, adopting instead an “empirical” taxonomic approach, such as one of the various rating systems that has utilized statistical methods to derive “factors” from the many possible observed or reported behaviors and symptoms, with the notion that the symptoms will converge into meaningful patterns or profiles that hang together statistically. Although this approach can be a useful initial tool for descriptive purposes, as a full-fledged classification tool it falls far short on a number of fronts. For example, such methods do not yet have a satisfactory way to obtain information from all possible informant sources and to reconcile that information when inevitable discrepancies arise. Whose report is to be trusted?

Consider a given youth, where rating scale information from parents, teachers, and the youth herself indicates no recent symptoms of depression or suicidal ideation, but the youth's best friend confides to the school counselor that the youth is storing up *more* pills to “really end it all” this coming weekend. When confronted by the school counselor with the best friend's information, the youth admits to feelings of hopelessness and “no way out,” to an earlier attempt that left her nauseated 2 weeks earlier, and to the presence of a now likely fatal cache of pills stored in her school locker. How meaningful could a classification sys-

tem be if based on methods that do not have means to incorporate such information and consider and reconcile discrepancies in order to obtain a more valid picture of the youth's feelings and behaviors? Or to consider additional complicating factors, such as the teen's desperation over the sexual abuse she is experiencing at the hands of an older brother, versus another teen who experiences the same wish to end it all, but without any identifiable precipitating circumstances other than a family history of teenage-onset depression in the mother and maternal grandmother.

Regardless of whether one uses a *DSM-IV* approach or an empirically derived taxonomic approach (e.g., see Achenbach, 1995), a more in-depth understanding of the possible circumstances surrounding each of these two instances of depression would remain obscure to either approach. Most certainly, effective service interventions would differ between these two examples. Actual service methods might overlap between the two cases (e.g., psychotherapy, medication) but still not be totally synonymous, because the former example would require a quite different approach to intervening with the family.

Definition of Disorder by Impairment Status

The most common cutoff applied to determine mental disorder caseness is the construct of impairment, such that in order to be a true case of disorder, one must suffer from some degree of impairment. This is an interesting distinction, and one not necessarily applied equally to other supposed disorders. Hypertension for many persons involves no apparent impairment, at least in the present tense, and treatment in asymptomatic persons is only employed because of the statistical likelihood of future impairment (disability or death) as a result of the untreated condition. In fact, the treatment itself is likely to result in side effects that could be reasonably construed as impairments.

Even accepting the need for impairment, the problem of determining the precise cutoff for the degree of impairment is inescapable. A number of strategies have been employed to minimize the numbers of false positives and false negatives (Hsiao, Bartko, & Potter, 1989; Lahey et al., 1994; Piacentini, Cohen, & Cohen, 1992), but such strategies must still rely on some other criterion against which the determination of a false positive or negative is made. How much impairment, and as judged by whom? Although the requirement of impairment seems a comfortable position at first glance, close inspection reveals that the many definitions of impairment can yield dramatically different rates of disorder (Angold et al., 1999).

In part, the current requirement for impairment as embodied in the *DSM-IV* stems from the fact that for mental disorders among both adults and children, we have no sure knowledge of the *underlying disease processes*. Just as with hypertension or with the presence of an asymptomatic malignant tumor, although neither result in current impairment, both are known to have certain consequences if left untreated, hence medical necessity is generally taken for granted. From a symptomatic perspective, these might be viewed as analogues to mental disorders' subthreshold conditions. For example, once we have obtained reliable markers for the likelihood of future onsets of Autism or Schizophrenia, prevention and early intervention strategies become possible. Eisenberg (1995) has noted that as science progresses, so do our assumptions of what constitutes mental disorder. Over 100 years ago, knowledge of hemoglobinopathies such as thalassemia was limited to the overt description of the clinical phenomenology of symptoms and affected bodily organs. After decades of research, precise knowledge of the point mutations in the molecular structure of the hemoglobin molecule underlying these conditions is now available, and persons totally asymptomatic can be identified and are considered cases from the perspective of prevention, early intervention, and genetic counseling. With time, better knowledge of the basic neural, psychological, and social processes underlying the mental disorders should allow us to worry less about what should be a case and more about the health merits, the appropriate services, and the ethical issues involved in intervening with an illness process that is reasonably well understood.

Pragmatic Approaches

To avoid the conceptual problems noted earlier and to answer the question, When is a case a case? we suggest that the first question that must be addressed is, A case for what purpose? For example, Sonuga-Barke (1998) notes that to distinguish between various definitions of disorder, one must clarify whether one wishes to define mental disorder for purposes of the clinical utility of such a definition (the pragmatic view) or the construct validity (the ontologic view). Although the ultimate goal of classification is *usefulness* (Frances, 1998), as Eisenberg (1995) has noted, there are many "usefulnesses." What works for researchers to define some presumably homogeneous entity (i.e., the attempt to "carve nature at its joints") may not work well for clinicians and policymakers, who often wish to know, Who needs care?

One potential route out of such an impasse has been described by Zarin and Earls (1993), who have recommended that methods of decision analysis be applied to such issues. They note that the essential components of diagnostic decision making—choice of external validator, choice of discriminator, and choice of cutoff scores—might be implemented very differently, depending on whether the clinician's or investigator's objectives are to (1) determine which children need psychiatric care and where overall assessments of disability are most relevant; (2) determine what clinicians do in real-world practice, that is, services research, which often varies from the ideal world of academic practice; or (3) determine which children are valid cases of a specific disorder for purposes of research into etiology, genetic factors, treatment response, and likelihood of persistence/recurrence. Thus, Caseness for what purpose? is the relevant question, and it must be appreciated that any cutoff or discriminator will result in some false negatives and false positives. The choice of cutoffs will often depend on the relative costs of false negatives versus false positives, vis-à-vis the clinical or research objectives.

Rather than reifying mental disorder as simple symptom counts that cross some relatively arbitrary threshold, Rogler (1993) suggests that, within given cultures, a quick decision with substantial face validity can be accomplished for many purposes to avoid attributing symptom, case, or impairment status to conditions or situations that actually reflect some form of goal-directed, culturally situated behavior. Although this is eminently sensible, we are unaware of any systematic testing of such approaches to determine if they can be reliably done, and whether multiple, culturally informed raters would agree among themselves with such face valid decisions. This recommendation harkens back to the etiological diagnostic formulations of previous *DSMs*, yet such an approach, if cautiously implemented, even in Anglo-American cultures, may help avoid according mental disorder status to some conditions that many would regard instead as adaptive responses (e.g., certain forms of Conduct Disorder; Richters & Cicchetti, 1993). Such an approach may also avert criticism that our diagnostic approaches too often ignore the obvious (Jensen & Hoagwood, 1997).

In an important sense, expert clinicians' judgments concerning symptom, impairment, and mental disorder status that make use of all available data over time constitute a not easily replaced "LEAD" ("longitudinal," "expert," and making use of "all data") (Spitzer, 1983), if not gold standard. Yet, such judgments, too, are situated in culture and time, reflecting in part both scientific findings and cultural

norms (Eisenberg, 1995). As culture changes or science advances, these determinations do as well. To this extent, the judgment of what constitutes a case (in terms of medical necessity or need for treatment) can never be fully satisfied by statistical approaches or complex equations and must instead take into account societal values, willingness to pay, determination of what constitutes a "problem in living" versus a disorder (such as the boundaries between transient sadness and Major Depressive Disorder), as well as the assembled experiences and norms of the families seeking care for their children and the mental health care providers within that cultural context. Without some metric that has been carefully calibrated to take into account these dimensions, any determination of mental disorder (apart from scientifically established qualitative differences in underlying disease processes) must remain more or less arbitrary.

CONCLUSION AND FUTURE PERSPECTIVES: NEED FOR A NEW PARADIGM

An overarching concern relates to the fact that in the area of child psychopathology, most well-documented risk factors appear to be common to most disorders; that is, the presence of any risk factor rarely has been found to be specific for any given disorder (Sameroff, Seifer, Barocas, Zax, & Greenspan, 1987; Werry, Reeves, & Elkind, 1987). Furthermore, as a general rule, treatments are not diagnosis specific but are symptom and context specific. These facts, coupled with what we know about the malleability of the early organism and the sensitivity of the brain to early environmental influences, suggest that we should work to move beyond static or descriptive models for understanding childhood psychopathology, such as embodied in our *DSM* classification approaches.

Developmental Psychopathology Models

In contrast to the behavioral, quasi-descriptive models of psychopathology, theorists with a developmental perspective working with infants, children, adolescents, and adults are usually keenly interested in the *processes* whereby behavior unfolds and in understanding how any particular form of psychopathology is molded by environmental input. Developmental approaches to psychopathology begin from the premise that it is essential to understand the complex historical pathways of an evolving organism that is attempting to master the tasks and demands imposed by the environment, as these environmental inputs and individual

responses simultaneously shape new organismic capacities. From this perspective, the descriptive state of psychopathology or dysfunction presumed intrinsic to an individual is no more salient than the nature of the transactions of the individual with the environment and the extent to which these transactions enhance or broaden the individual's behavioral repertoire for future environmental transactions and task mastery. Viewed from a developmental psychopathology perspective, understanding the processes of adaptation over time within a continuously unfolding, ever-changing context is essential.

Developmental approaches to psychopathology often seek to examine dysfunction not as a state of *being* of the individual, but as an epigenetic pattern of transactions of the organism with the environment. Some pathologic patterns (though potentially adaptive in the immediacy) can lead to increasing oscillations in the child's (or adult's) performance of age-appropriate social and cognitive tasks, may eventually lead to increased difficulties that generalize beyond the immediate domain or sphere of functioning, and may increase the likelihood of emerging disabilities/impairments in other areas of function. Although even this developmental approach also runs the risk of becoming a tautology, this perspective suggests that impairment or loss of capacity in performing age-appropriate, cultural- and context-specific tasks might constitute an additional, useful criterion to establish the presence of psychopathology. Of course, an age-referenced measure of impairment alone constitutes an insufficient criterion for psychopathology, because it ignores the person's family and current history, pattern of experiences, and current circumstances. Yet, this criterion can be seen as increasingly salient when the loss of capacity can be demonstrated to be relatively enduring and/or permanent, and potentially can lead to other disabilities or incapacities across other contexts, as the increasing demands of the environment, the exigencies of the developing organism, and the relative incapacities collide.

Of note, the measurement demands required to assess a dynamic relational system do not conform a priori to either dimensional or categorical approaches to assessment of psychopathology. In fact, a significant limitation to both of these approaches as typically employed is that they presuppose that that which is being assessed lies within the given individual. The categorical and dimensional approaches each have advantages and disadvantages as well as a generous number of adherents (Cantwell, 1996), but a unilateral focus on either approach to the exclusion of careful assessments of the transactions over time between individuals

and their environments will fail to capture the context-rich processes that are needed for an integrative understanding of the phenomenon.

Thus, taking a step back, we suggest that questions of an *essentialist nature*, such as, What is *the* core cause of this behavior problem? or What is the "true" prevalence of this disorder? are inappropriate for a system that cannot classify behaviors into essential categories. If this is not or cannot be the goal, then it is appropriate to ask, What question does the classification system answer? What is the purpose of classifying? Within the scientific framework that we advocate, we suggest instead that studies of a given behavior (or disorder) should begin from the operational assumptions that there will likely be significant individual differences in the manifestations of these behaviors, that they will be derived from many different etiologies, and that they will express themselves quite differently in different contexts and transactions with the environment (Cicchetti, 1987). As a further step in reconciling some of the difficulties in our current diagnostic approaches, we suggest that there is a need for a more avowedly open, self-critical, developmental stance toward our diagnostic entities. Greater awareness in the research and clinical communities is essential to avoid the reification of psychiatric labels and to enact a more etiologically based process and context-elaborated nosology.

Need for a Typology and Theory of Contexts

Although we are critical of the limitations of the current diagnostic systems, these criticisms should not imply the need to return to past systems based on unsubstantiated or untestable theories. Instead, careful description and operationalization of *all* relevant phenomena are needed. These include individual symptomatic, functional, family-interactive, past history of services or treatments and response to them, contextual and longitudinal-historical phenomena. These processes, if captured fully, can yield an informative database able to characterize disordered processes and functions. As others have argued (Boyce et al., 1998; Sadler & Hulgus, 1994; Trickett, 1996), a major limitation of the characterization of persons in contexts has been the absence of a typology and adequate theory of context. The *DSM-IV* Axis IV (level of stressors within the past year) is a modest beginning, but a broader and more rigorous approach to assessment and toward a contextual nosologic system is needed. Sadler and Hulgus (1994) suggest that a nosology of context could provide the structural form for patients' unique historical and

environmental backgrounds and offer a methodology to combine diagnostic and contextual information for individual subjects. Such a typology could expand our search for disorders and psychopathology to environmental and historical contexts for a given individual and ensure that clinically salient life events are incorporated into treatment planning. Nosologic practices would thereby better reflect salient psychosocial factors along with person-based psychological and biological factors to understand individuals' outcomes. Sadler and Hulgus (1994) suggest three levels for the development of a contextual nosologic system: (1) syndromes of personal history (e.g., early parental death, incest); (2) syndromes of the interpersonal environment (e.g., victimization, divorce, death of spouse); and (3) syndromes of the extrapersonal environment (e.g., media influence, catastrophe, homelessness, loss of employment). Of note, more explicit operationalizations of such criteria are now emerging (e.g., see Dausch, Miklowitz, & Richards, 1996; Group for the Advancement of Psychiatry, 1996), but they are still very much at the beginning.

Other authors have suggested that more attention be paid to the culture-specific presentations of individual symptoms as a function of the individual's larger social environment (Trickett, 1996). For example, Alarcon (1995) describes the development of recommendations in the *DSM-IV* that included cultural statements in the introduction, cultural considerations for each diagnosis, and so on. These recommendations are a first step, but they are a modest step indeed, given the strong evidence for culture-bound syndromes and the misapplication of diagnosis to different cultural and ethnic communities. As Alarcon notes, less favorable diagnoses are frequently applied to poor ethnic communities, and any diagnostic system (including the *DSM-IV*) runs the risk of becoming a vehicle of an ethnocentric view of mental disorder. Such problems can partly be addressed by developing an international item pool to permit alternative classification of cases using mutually compatible instruments and translations of concepts, but these recommendations still fall short of careful specification and description of ordered and disordered processes (as in the theory and measurement of attachment).

Rogler (1993) notes the need for careful examination and attention to symptoms and their characterization at three levels: (1) the assessment of symptoms and their meanings, (2) the patterning of symptoms and their disorders, and (3) the interpersonal context of the diagnostic interview process itself. Thus, symptoms may be part of one cultural context but may not qualify as symptoms per se in another setting (e.g., devoutly religious persons hearing the

voices of recently deceased relatives). Maximum diagnostic error is likely to occur when a category developed in one culture is applied to another. Thus, the construct of Conduct Disorder, though potentially useful in a clinically referred population for both treatment and research, may be quite problematic when used to characterize children in the community from another cultural or ethnic background (Richters & Cicchetti, 1993). Moreover, studies suggest that even though the criteria for conditions such as Conduct Disorder do not fully take context into account, clinicians consider these factors nonetheless when presented vignettes that differ by social context and asked to judge whether the described youth does or does not have a mental disorder (Kirk & Hsieh, 2004).

Application of Multiple Methods and Conceptual Frameworks

Another way to address the difficulties with the current diagnostic and nosologic systems is to approach the problem with multiple conceptual frameworks and methodologies. For example, Maton (1993) advocates the use of linked ethnographic and empirical methodologies, and Weisner (1996) argues that ethnographic methods are the most important approach to understanding individual functioning. Although ethnographic approaches have their own limitations (including subjectivity, potential unreliability, sampling bias, and replicability), problems with quantitative methods include the lack of validity of the construct and its measurement derived from one person or setting and applied to another, where important constructs and patterns of a given cultural setting are ignored. Ideally, quantitative and qualitative approaches must be linked and used together. Both constitute critical tools in understanding disordered processes and mental illness (Shinn, 1990; Trickett, 1996; Weisner, 1996).

Through a systematic application of methodologies that capture interactional processes and that reflect the variety of different perspectives about psychopathology, we believe it will be possible to elucidate a common underlying developmental or pathogenic process. In this way, it should be possible to improve understanding of what criteria validate mental illness, in much the same way that an internist applies understanding about an internal pathophysiologic characteristic (e.g., elevated blood pressure) to define a latent illness state, even though the person is currently asymptomatic. Thus, Kleinman (1988) has suggested that the validity of psychiatric diagnoses should involve a conceptual and iterative tacking back and forth between the

psychiatric diagnostic system and its rules of classification, alternative taxonomies, clinical experience, the patient's interpretation, and the cultural and historical contexts in which the diagnostic system, words, languages, and meaning are situated. In other words, in the absence of firm biologic demarcations, a diagnosis is an interpretation, and its ultimate validity must be indexed by reference to the cultural norms, values, and languages of a particular society, as well as the environmental demands and constraints of a person's particular contexts.

Given the fluidity of language, meaning, and contexts in human society, as a general rule diagnostic systems and assessment approaches should be understood as more or less arbitrarily and temporarily constructed systems to further scientific investigations (Popper, 1994; Wiggins & Schwartz, 1994). The use of current systems to inform reimbursement procedures and decisions about who should receive care may operate at odds with one another. Under some conditions, different systems may be needed for different settings and purposes.

As a note of caution, Jablensky (1994) points out that all classificatory efforts to date based on primary essences (e.g., disordered process, etiology, genetic pattern course, or response to treatment) have not fared well, compared to more eclectic approaches, which have generated a fair amount of innovative research and have found useful and practical applications.

Closing Comments

Studies of language, meaning, and the history of science indicate that the reasons for the construction of any classification system determine the kinds of questions that may be asked of the items within it. Language is a system of signs, and the language of classification systems *constructs* (rather than discovers) meaning. Such constructions set parameters on the kinds of questions that can legitimately be asked of the categories into which "normal" and "abnormal" behaviors are divided. Studies of language suggest that the meaning of language is not fixed but changes as its production and use changes. Likewise, the changing positions of psychiatric diagnoses within prevailing social notions of what constitutes disease and mental illness suggest that socially specific events can produce fluctuations in diagnostic categories, as language, its meaning, and use change over time.

Given what we know about early plasticity and children's responsiveness to environmental modifications and the counterintuitive and atheoretical nature of current

nosologic systems, alternative (and better) ways to understand these phenomena of childhood behavioral and emotional disturbances are needed, as opposed to the simplistic notion that disorders reside within persons. Many of our mental disorders might be reconceptualized to reflect interactions between brain and environment and the consolidation of these interactions over time (Garruto, Little, & Weitz, 2004). Thus, psychiatric disorders are the result of not just environmental factors, nor of biologic factors exclusively. Rather, disorders are the result of the progressive development of the brain as it unfolds within the constraints of the genomic map and the particular environmental circumstances and context of a given organism in a particular history. Such an approach, if supported by robust measures and analytic methods, is more likely to lead to a closer approximation of the underlying developmental processes, as well as provide opportunities for timely service, treatment, and preventive interventions.

In this chapter, we discuss developmental psychopathology from the viewpoint of epidemiology, “the study of health and illness in human populations” (Kleinbaum, Kupper, & Morgenstern, 1982, p. 2). After a brief introduction to some of the basic concepts of the epidemiological method, we discuss what modern epidemiology is and does, what questions it addresses, some of the key methods it uses, and how these methods can be applied to the special problems of developmental psychopathology. We present a short history of how child psychiatric epidemiology has grown into developmental epidemiology, illustrating how these changes reflect society’s changing concerns about the mental health of children. In the final section, we describe some of the

The work reported here was supported in part with grants from the National Institute of Mental Health (P30-MH57761, R01-MH063970, R01-MH01002, K02-MH01167), the National Institute on Drug Abuse (R01-DA011301, R01-DA016977), and the William T. Grant Foundation.

ways developmental epidemiology is branching out and taking on the concerns and methods of related areas: life course and intergenerational epidemiology; transnational epidemiology; genetic epidemiology; the study of burden of disease, including the economic costs of psychiatric illness; and the use of epidemiologic designs to test hypotheses about the causes of psychiatric disorders.

By the end of the chapter, we hope to have made the case that (1) the goal of epidemiological research is disease prevention; (2) understanding the development of a disease and intervening to prevent and control it are equally important aspects of epidemiological research; (3) understanding the development of a disease may point to different kinds of intervention at different stages in the developmental process; and (4) understanding individual development is a critical part of understanding and intervening in the disease process, because both risk for and expression of disorder change over the life course.

WHAT IS EPIDEMIOLOGY?

Epidemiology is the study of patterns of disease in human populations (Kleinbaum et al., 1982). Patterns, or nonrandom distributions, of disease occur in both time and space. The task of epidemiology is to understand observed patterns of pathology along these two dimensions and to use this understanding as a basis for prevention and treatment. For example, a pattern has been observed linking exposure to environmental lead in infancy with the development of behavioral and learning problems in later years (Needleman & Bellinger, 1991). The causal relationship appears to be sufficiently strong to justify primary preventive measures to remove lead from gas and domestic paint to protect those children who might otherwise be vulnerable to such exposures.

Epidemiology, “an exact and basic science of social medicine and public health” (Earls, 1979, p. 256), emerged as an influential branch of medicine in the nineteenth century. Like the rest of medicine, it is an action-oriented discipline, whose purpose is intervention to control disease. Epidemiology has both similarities to and differences from clinical medicine. Scientific knowledge about the cause and course of disease is one of the tools that both share. Epidemiology reflects clinical medicine also in using two methods of attack: a tactical method, concerned with the practical and administrative problems of disease control at the day-to-day level, and a strategic method, concerned with finding out what causes disease so that new weapons of control and cure can be engineered (Earls, 1980; Susser, 1973). Thus, epidemiologists can be found, in their tactical or public health role, reporting on the prevalence of AIDS and advising on how to control its spread, while, at the same time, as part of a wide strategic plan to control the disease, they are carrying out multicenter clinical research trials of new vaccines and treatments.

Epidemiology is also like clinical medicine in its understanding of the concept of disease in broad terms. In this chapter, we adopt the definition of disease as a pathological process, which may have biological, psychological, and social dimensions (Kleinbaum et al., 1982; Susser, 1973). Disease in this sense includes, but is by no means limited to, identified syndromes of known etiology. The unifying theme is that, at some point, a decision is made that a pathological process is present in an individual, who is then regarded as a “case.” The thorny problems of case identification in child and adolescent psychopathology are discussed later in this chapter.

Epidemiology *diverges* from clinical medicine to the extent that it concentrates on understanding and controlling

disease processes in the context of the population at risk, whereas the primary focus of clinical medicine is the individual patient. This does not mean that epidemiology is not concerned with the individual; on the contrary, it is very much concerned with understanding the individual’s illness and the causes of that illness. The difference lies in the frame of reference. Put crudely, clinical medicine asks What is wrong with this person and how should I treat him or her? Epidemiology asks What is wrong with this person and what is it about him or her that has resulted in this illness? Why is this child depressed, but not her brother? If her mother is also depressed, is the child’s depression a cause, a consequence, or an unrelated, chance co-occurrence? Such questions immediately set the individual child within a frame of reference of other children, or other family members, or other people of the same sex or race or social class. As we shall discuss later, this approach to understanding pathology has important effects on the way information is collected, the kind of information collected, the methods used to analyze it, and the conclusions that can be drawn from it.

As the study of patterns of disease distribution in time and space, epidemiology thus encompasses a great deal more than simply counting how many people have smallpox or AIDS. “Epidemiology counts” (Freedman, 1984, p. 931), but it does far more than that. The methods developed to count cases are useful for many purposes, for example, to estimate the need for and probable cost of mental health services, or to monitor the effect of a new treatment. However, these methods provide only one part of the information needed to understand the course, causes, and prevention of disease. Figure 3.1 (Kleinbaum et al., 1982) shows how the study of disease patterns in time and space informs both public health and scientific epidemiology (Susser, 1973).

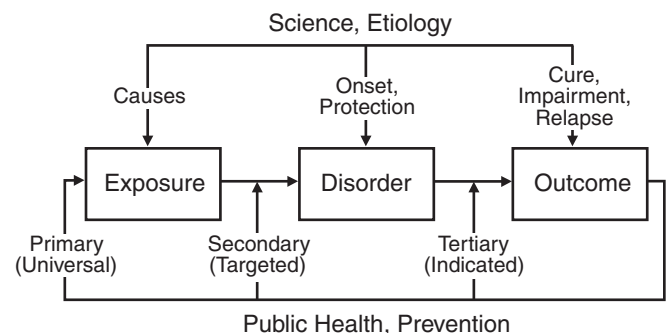

Figure 3.1 Model of the relationship between scientific and public health epidemiology.

Scientific Epidemiology

From the strategic or scientific point of view, the issues at each level have to do with identifying the stages by which a disease progresses through its natural course, generating and testing hypotheses about causal pathways, and inventing and testing methods for prevention to be implemented by the tactical, public health arm of the health care professions. The success or failure of attempts to prevent a disorder can then provide important information about the causes of the problem. The course of disease can be divided into three stages: (1) exposure, dealing with causes; (2) disorder, dealing with the manifestation of a disease in clinical signs and symptoms; and (3) outcome, examining what leads to different outcomes for different patients. These three stages invite different kinds of preventive intervention: (1) primary, or universal, prevention tries to reduce the risk of exposure to agents promoting the disease; (2) secondary, or targeted, prevention is directed at saving those who have been exposed from developing the disease; and (3) tertiary, or indicated, prevention focuses on reducing the damage caused in those who actually become ill. Tertiary prevention encompasses both reducing the residual damage from an illness and, where necessary, protecting the rest of society from harm, either through infection or from a sick person's dangerous behavior.

Although this approach to disease prevention was first articulated at a time when acute, infectious diseases such as cholera and smallpox were the chief preoccupation of epidemiology, it applies with minor modifications to chronic or episodic diseases, such as heart disease and cancer, which are the main causes of mortality in industrialized countries today. Applied to psychopathology, it also provides a model for exploring the development of psychiatric disorders (Rutter, 1990).

Public Health Epidemiology

At the tactical level, public health and primary care workers are often involved in what has been called "shoe-leather epidemiology" (Kleinbaum et al., 1982, p. 25). This might take the form of tracing the pathways by which a cluster of suicides spreads through a high school, or isolating the source of a neurotoxic element in the water supply, or teaching lifestyle changes to cardiac patients to reduce the risk of stress-related disease. The aim is to identify key points in the development and transmission of a disease at which intervention can act to reduce the prevalence of the disease or the harm caused by it. Such interventions may be directed at preventing exposure to the causes of the disorder,

at preventing the onset of the disorder in those who are vulnerable to it, or at minimizing death rates or residual impairment in those who survive. Taking depression as an example, primary prevention might include antibullying programs in schools; secondary prevention might be directed at the children of depressed parents, who are known to be a high-risk group (Clark et al., 2002); and tertiary or indicated prevention might examine the ability of adequate treatment to prevent relapse.

There is a great deal of interchange between the public health aspects and the scientific aspects of epidemiology, and also between different levels of investigative and preventive effort. At each of these levels, both strategic and tactical efforts are needed. Indeed, the real-world nature of epidemiology means that the answers to many scientific questions, such as the paths of disease transmission, have at some stage to be tested by regarding a preventive intervention as a scientific experiment. The classic example is the story of how John Snow (1855), by having the handle removed from the Broad Street water pump during the 1853 cholera epidemic in London, tested his hypothesis that (1) cholera was caused by an invisible, self-reproducing agent living in water; (2) the agent flourished in water heavily contaminated with sewage; and (3) therefore, if a community drawing its water from a contaminated supply was forced (by his action in disabling the pump) to use water from a different water company, drawn from a purer source, the rate of disease would fall.

CHARACTERISTICS OF RESEARCH IN PSYCHIATRIC EPIDEMIOLOGY

Epidemiology, as this brief introduction demonstrates, is less a body of substantive knowledge than it is a way of looking at problems. The great historical victories over infectious diseases and the recent achievements in helping to reduce mortality and morbidity from chronic illnesses such as cardiovascular disease (Dawber, 1980) came as a result of looking at clinical problems in a new way. Here we introduce the basic requirements for studying the epidemiology of any disorder (Kleinbaum et al., 1982) and discuss their implications for developmental psychopathology.

Epidemiologic research presupposes the ability to (1) measure disease frequency in the population of interest; (2) make valid generalizations from samples to populations; that is, to avoid sampling or ascertainment bias; and (3) measure the impact of risk factors on disease without confusion among multiple competing risks; that is, to avoid

confounding among risk factors. We discuss each of these challenges in turn.

Measuring the Frequency of Disease

The question of how many people exposed to a risk factor for a disease actually become sick, how many avoid disease, and how many die or recover is central to epidemiological research. The most frequently used measures involve the concept of a rate, “an instantaneous potential for change in one quantity per unit change in another quantity” (Kleinbaum et al., 1982, p. 3). Timing is implicit in the idea of a rate. Epidemiology deals most often with incidence rates, which measure the extent to which new cases of a disorder appear in the previously healthy population over a specified period of time, and prevalence rates, which measure all the cases, whether new or previously existing, observed during a specified period. Usually, the epidemiologist is concerned with relative rates of disease onset in two or more groups of people who differ on exposure to a risk or preventive factor. For example, in a Swedish study, the prevalence of drunkenness in adolescence among girls who reached menarche earlier than the norm for the population was found to be high, relative to the rate found in girls of the same age whose menarche occurred within the normal age range (Stattin & Magnusson, 1990). Relative rates thus become the metric for answering questions about a possible causal role played by putative risk factors in the onset of disorder. In this example, Stattin and Magnusson found that, at age 14, 75% of girls who had reached menarche before age 11 had been drunk at least once, compared with only 29% of girls who reached menarche after age 13. Furthermore, the rate of frequent drunkenness remained higher across adolescence for early than for later maturing girls. This led to speculations about the mechanism by which early puberty could put girls at risk (Moffitt, Caspi, Belsky, & Silva, 1992).

Defining a “Case”

In any context where decisions have to be made leading to action to prevent or treat illness, categories have to be created. Making a diagnosis means putting an individual into a category: “Has Disorder X” or “Does not have Disorder X.” Even if the goal is to eliminate a risk factor that potentially affects everyone in the community, such as environmental pollutants or unsafe automobiles, it is still necessary to define categories of affected and nonaffected individuals to measure the effectiveness of a primary prevention or to calculate costs and benefits; for example, how many cases of learning disability were prevented by reducing environmen-

tal lead? How much does it cost to prevent one case of learning disability, and how much is saved by doing so?

The relationship among symptoms, diagnosis, and the concept of disease has exercised many brains (Meehl, 1992; Pickles & Angold, 2003). A diagnosis encapsulates a mixed bag of information: the number and severity of symptoms, the duration of symptomatology, the date of onset, the likelihood of exposure to a causal factor, and the level of functional impairment. All of these have implications for a decision about whether intervention is indicated. For some forms of pathology, there is little ambiguity about how the diagnosis should be made; either it is fairly self-evident, like a broken bone, or the rules have been sanctified by use, like the stages of cervical cancer, or there is a clearly identifiable pathogen that acts as a marker for the disease, as in tuberculosis. Few types of psychopathology can invoke any one of these as a decision rule for diagnosis. There are no reliable pathognomic markers; the boundaries between one disorder and another, or between normality and disorder, are generally ill-defined (Pickles & Angold, 2003), as Kendell (1976) demonstrated in his classic exploration of the boundaries of depression. Classification systems arise and pass away, while older classifications may still retain some of their sway. To confuse matters further, psychiatry often makes use of familiar language in its diagnostic terminology (e.g., “depression,” “anxiety”), not necessarily in the vernacular meaning of the term. In his review of childhood depression, for example, Angold (1988) identified eight different ways the term “depression” is used in the description of psychopathology:

- As the low end of normal mood fluctuations
- As a description of psychic pain felt in response to some unpleasant situation
- As a trait
- As an individual symptom
- As a syndrome
- As a disorder
- As a disease
- As a cause of handicap or disability

The implications for treatment are likely to differ, depending on which definition is being used.

Taxonomy, Instrumentation, and Mechanisms

In identifying cases of a disorder, it is important to distinguish between the problems that can be solved by a well-designed diagnostic instrument and those that have to be solved at the level of the taxonomic system that defines what a case is (Meehl, 1992; Wing, Bebbington, & Robins,

1981). For example, L. N. Robins (1989) presented evidence that some *DSM* disorders are consistently diagnosed more validly (using several criteria of validity) than others, using both clinical and epidemiological methods. This, Robins believed, suggests that “part of the source of invalidity lies in the diagnostic grammar of the systems whose criteria standardized interviews evaluate” (p. 57). She used the phrase “diagnostic grammar” because, she argued, “[diagnosis] is much like a language. The criteria include elements that have special relations to each other like parts of speech—symptoms (nouns?); severity (adjectives?); clustering (verbs?); age of onset, frequency, and duration (adverbs?)” (p. 61). If the grammar is wrong, the sentence will not make sense, however clearly it is articulated. Much of the process of developing a good diagnostic grammar is carried out through careful clinical work. Epidemiology, however, can contribute in several ways. It provides feedback about the relationship between symptom patterns seen in clinical and community samples, which can throw light on possible biases affecting the results (see later discussion). It can also provide information about the prevalence of different disorders in the community and their patterns of distribution by age, sex, and so on. This information can then influence clinicians’ expectations about the relative likelihood that a given patient has one disorder rather than another. In practice, it is well-known that physicians make diagnostic judgments on the basis of very few items of information (Cantwell, 1988; Meehl, 1954). Good prevalence information can be a very important part of the clinician’s database.

Psychiatric epidemiologists have long been active collaborators with clinicians in the work carried out around the world to improve psychiatric taxonomies (L. N. Robins, 1985, 1989). However, the task facing epidemiology is even more difficult than that facing clinical psychiatry. The clinician can assume a certain level of suffering in a patient who has come seeking help; the problem is to figure out exactly where the suffering lies. Epidemiologists, working most of the time in the community, have to identify cases among people most of whom are not seeking treatment. They have to convince themselves and others that the criteria they use are valid: that a clinician would identify this person as a “case” of a given disorder whether or not the individual came seeking treatment.

For child psychiatry, this problem of case definition is even more complex. Children rarely refer themselves for treatment, even when severely symptomatic. Thus, the rule of thumb that equates illness with seeking treatment is even less accurate for children than it is for adults. Refer-

ral for treatment may have more to do with characteristics of a child’s mother, teacher, or pediatrician than with the child’s own behavior or feelings (E. J. Costello & Janiszewski, 1990; Dulcan et al., 1990; Shepherd, Oppenheim, & Mitchell, 1971).

A third aspect of case identification is the discovery of mechanisms that underlie the development of psychiatric disorders. These mechanisms exist at many different levels, from genes to brain structure and functioning. Despite much exciting progress in identifying mechanisms (discussed later), none is yet ready for use in everyday clinical or epidemiologic diagnosis. Child psychiatry is still largely dependent for case identification on asking verbal questions.

Using Question-and-Answer Methods to Identify Cases

Psychiatry confronts two problems that make it particularly difficult to develop reliable and accurate measures of symptoms and diagnoses using question-and-answer methods. One is that there are no “gold standard” measures that can be used to evaluate the accuracy of a test: a post-mortem or an MRI will not tell us whether a child really had Separation Anxiety Disorder. The second problem is with the standard procedure for assessing the reliability of a question-and-answer measure: the test-retest reliability procedure, which uses two interviewers to interview the same subject on two different occasions about the same period of time. Whereas one can take someone’s temperature repeatedly without appreciably altering body temperature, interviewing someone at length about emotionally sensitive topics can hardly be done without affecting how the individual thinks or feels about these issues. The first interview is thus likely to affect how the subject responds to the second interview. For example, in a test-retest study in which children were interviewed twice, we found that boys who, at the first interview, admitted that they told a lot of lies, were much more likely than other boys to deny, at the second interview, other kinds of deviant behavior to which they had previously admitted (Angold & Costello, 1995). However, a lot is now known about how to improve accuracy in child psychiatric interviewing, and current methods are remarkably reliable (Shaffer, Lucas, & Richters, 1999).

Classifying Cases in the Clinic and the Community

The problem of equating cases found in community studies with referred cases has been addressed in several ways in child psychiatric epidemiology. First, diagnostic instruments have been developed that meticulously translate clinical diagnostic criteria into methods for identifying the same

symptoms in nonreferred cases (Angold & Costello, 2000; Angold, Cox, Prendergast, Rutter, & Simonoff, 1992; Chambers et al., 1985; A. J. Costello, Edelbrock, Kalas, Kessler, & Klaric, 1982; Herjanic & Campbell, 1977; Hodges, McKnew, Cytryn, Stern, & Kline, 1982; Shaffer, Fisher, Lucas, Dulcan, & Schwab-Stone, 2000).

Second, most measures for community use now include, or are used with, measures of functional impairment, so that the relationship between symptoms and a child's ability to carry out the normal tasks of daily life can become the subject of empirical review. At the same time, current attempts to classify psychiatric disorders into a coherent taxonomy have adopted a multiaxial system by which a clinician is encouraged to describe the patient from several points of view, of which psychiatric diagnosis is only one (American Psychiatric Association, 1994; Rutter et al., 1969; Rutter, Shaffer, & Sturge, 1979). Several current epidemiological assessment instruments adopt the same multiaxial approach (Angold & Costello, 2000; Shaffer et al., 2000).

Third, the psychometric studies that are carried out as part of the process of instrument development include studies of referred and nonreferred samples and interviews using both clinicians and trained lay interviewers. Instruments can then be revised so that "caseness" has the same meaning wherever or by whomever a child is recruited or assessed.

Developmental Issues in Case Identification

One reason establishing rates of disorder is even more of a problem for child psychiatric epidemiology is that there is a need to reconcile a nondevelopmental psychiatric taxonomy, such as the *DSM* system, with the realities of child development. The *DSM* system sticks closely to an implicit medical model, according to which a disease, although it has a developmental course along the lines sketched earlier, is defined as a disease by virtue of the fact that every case has roughly the same etiology, pathogenesis, risk factors, presentation, course, and treatment response. Measles is measles. For example, the diagnostic criteria for *DSM-IV* Major Depressive Episode are described as being similar in their essential features in children, adolescents, and adults (American Psychiatric Association, 1994); the only differences specified are additions to two of the symptoms: "(1) depressed mood. In children and adolescents, can be irritable mood" and "(3) significant weight loss or weight gain. . . . In children, consider failure to make expected weight gains" (p. 327). A section on age-specific features of depression (p. 220) discusses symptoms or forms of comorbidity with other disorders that may occur with different frequency at different ages, but no ref-

erence is made to any aspect of children's cognitive, social, and bodily development that might influence a child's ability to experience or respond to different symptoms. Neither the similarities nor the differences specified by the *DSM* have a firm basis in developmental data about the manifestation of depression at different stages of life (Angold & Worthman, 1993; Cicchetti & Schneider-Rosen, 1984, 1986; E. J. Costello et al., 2002; Digdon & Gotlib, 1985).

In summary, epidemiology shares with clinical psychiatry a concern for and involvement in the problems of case identification. These problems occur at two levels: the level of defining the characteristics of a disorder and the level of developing methods for identifying those who have the disorder so defined. Arguments about the reliability and validity of psychiatric assessment have frequently confused these two levels, as L. N. Robins (1985, 1989) has so clearly demonstrated. Only when we can clearly describe the causal pathway for each disorder, from exposure through onset to outcome, as in Figure 3.1, will we be in a position to be satisfied with the validity of our taxonomy and the reliability of our diagnostic tools.

Ascertainment Bias in Case Identification

Once researchers are able accurately to identify cases of the disorder of interest, the next concern is to ensure that the sample of cases that they recruit for research purposes accurately represents the distribution of cases in the community. The reason this is so important is the need for the relationship between the disorder and its putative risk factors to be the same in the sample as in the general population. It is the nature of epidemiological research that questions of causality can rarely be answered by laboratory studies in which all but the key variable are carefully controlled or randomly varied. It is not feasible to test the causal role of poverty, for example, by randomly assigning newborns to be raised in high- and low-income households, or the role of maternal temperament by the sort of cross-fostering studies that are considered ethical with other primates (Suomi, 1991). One way to compensate is to pay very careful attention to the characteristics of the population from which the study samples are drawn, that is, not only to the numerator of a rate of disease (the number of cases within a given period) but also to the denominator of the rate (the population at risk). Only when we know that the sample selected for study accurately mirrors the population from which it is drawn (or when we know exactly what the biases are and how to control for them) can we specify exactly to whom our causal analyses apply.

This necessity usually rules out samples of convenience and mandates very careful thought about the choice of population for a study. For example, if the question has to do with the causal role played by the peer group in adolescent delinquency, and the sample consists of young people recruited from 10th-grade classrooms, neither the denominator nor the numerator can, by definition, include persons who have dropped out of school. Thus, the conclusions about causal processes that can be drawn from such a study are limited to those relevant to 10th graders who attend school, not to the age group in general. Because dropping out of school and delinquency are known to be associated, the selection of a school-based sampling frame results in a sample that may be biased in important ways.

The problem of ascertainment bias is even more acute when clinic-based samples are used. There are many reasons people get into treatment, and reasons they do not, and these may mislead the researcher trying to understand risk factors for disease. For example, Berkson (1946, p. 50) used Mayo Clinic records to show that among people with two illnesses, “each disease is itself aggravated in its symptoms and more likely to be noted by the patient . . . [the] effect would be to increase relatively the representation of multiple diagnoses in the hospital and in general to increase the discrepancy between hospital and parent population.” This led to a spurious belief that cholecystic disease was causally related to diabetes, when in fact, in the general population the association between the two diseases was zero.

Berkson (1946) argued from these analyses that it is more cost-efficient to carry out representative community studies earlier rather than later in the process of studying comorbidity and etiology because bias-free studies have to be done at some point in any case. Meehl (1992, p. 124) is another writer who has pointed out that “millions of dollars of tax money have been wasted” performing studies in clinical settings where the biases inherent in case selection mean that the studies cannot answer the questions about causal association that they are designed to address.

The danger of ascertainment bias is one reason many epidemiological studies use samples that are carefully selected to be representative of the general population. The disease of interest may be quite rare in the community, which often means that the case-identification stage of such studies is expensive; large numbers of people must be surveyed to identify a relatively small number of cases. With child psychiatric disorders, the issue is compounded because reports from different informants—parents, children, teachers, peers—may identify very different children

as cases (Achenbach, McConaughy, & Howell, 1987; Rutter, Tizard, & Whitmore, 1970). Depending on the question being studied, it may be necessary to interview three or more people to establish whether a child is or is not a case according to the study criteria. The risk factors for a disorder identified by one informant may also be quite different from the risk factors for the disorder as identified by another informant. For example, in a study of children with symptoms of hyperactivity, inattention, and impulsivity (E. J. Costello, Loeber, & Stouthamer-Loeber, 1991), 61% of children identified as hyperactive by both parents and teachers were boys; however, boys made up 77% of children identified as hyperactive by teachers alone, but only 38% of children identified by mothers alone.

For the researcher interested in developmental influences on the expression of psychopathology, the situation becomes even more complex. For example, Figure 3.2 shows the rate of separation anxiety symptoms reported by children between the ages of 7 and 16 and by parents about their children. The parents’ report data showed low rates of symptoms and a modest effect of the child’s age on the rate of symptoms. The rate of symptoms reported by the children, in contrast, fell sevenfold as the age of the child increased. If the purpose of the study had been to select a sample of cases of Separation Anxiety Disorder, the bias caused by relying exclusively on one informant or the other would have varied depending on the age of the children surveyed.

Controlling Bias in Estimating the Influence of Risk Factors

The third set of threats to the validity of a causal link has to do with competing risk factors or confounders. In most

Figure 3.2 Mean separation anxiety symptoms by age and source of information. Data from the Great Smoky Mountains Study.

etiological studies, more than one risk factor is involved. The problem is to figure out the relative importance of various risk factors so that decisions about intervention can be focused where they will be most effective. It is useful to distinguish between two distinct characteristics of factors that influence the probability of disease: confounding and effect modification (Miettinen, 1974).

Confounding distorts the impact of a risk factor on the risk of disease because of the presence of some extraneous variable. A factor may act as a confounder in one study but not in another. Consider, for example, two groups at high and low levels of genetic risk for a disease that is also affected by poverty. If everyone in one group was at high genetic risk, a “real” relationship between poverty and disease might be obscured in that community; almost everyone who was poor would also be at genetic risk, so it would not be possible to say which factor was causing the disorder. In the second community, where not all the poor were at high genetic risk and not all the group at high genetic risk were poor, it would be possible to look separately at the rates of disorder in four groups (poor nonaffected, rich nonaffected, poor affected, rich affected) and figure the risk associated with poverty.

Effect modification, or synergy, refers to the different impact of a risk factor at different levels of another variable (Rothman, 1976). This relationship is not specific to any particular study; it is a “real” relationship among two or more risk factors. For example, if both the gene for phenylketonuria (PKU) and a diet high in phenylalanine are necessary for PKU to occur, rates of the disorder will vary in different communities depending on how many people inherit the gene and how many eat a high-phenylalanine diet. The relationship between gene and diet remains constant across sites, but diet will act as an effect modifier, controlling the expression of the gene. Another example is the relationship among peak height velocity (PHV, the “growth spurt” of early adolescence), change of school, and depressive symptoms. The period of PHV may be a time when youngsters are particularly vulnerable to symptoms of depression (Simmons & Blyth, 1987), particularly when they have to deal with stressful events. It happens that, in the American school system, most children move from middle school to high school between eighth and ninth grades. This coincides with the time when many girls, but few boys, are at PHV. School change could thus be acting as an effect modifier, increasing the risk of depression in girls but not in boys.

Clinical as well as epidemiologic research has to deal with confounders and effect modifiers. Lively debates are in progress about whether and how to derive causal infer-

ences from observational studies with many potential confounders (Dehejia & Wahba, 1999; Kaufman & Cooper, 1999; J. Robins, 1997; J. Robins, Greenland, & Hu, 1999; J. Robins, Hernan, & Brumback, 2000; Vineis & Porta, 1996; Weinberg & Umbach, 2000; Winship & Morgan, 1999). Sometimes it is possible to narrow down the list of potential causes using careful study design. When standard experimental designs are inappropriate or infeasible, quasi-experimental methods may be found that reduce the risk that cases and noncases differ not only on the putative risk factor, but in lots of other ways as well (Shadish, Cook, & Campbell, 2002). For example, in our study of all 9-, 11-, and 13-year-old American Indian children living on a federal reservation, it happened that after we had assessed the children for 4 years, a casino was opened that gave every enrolled tribal member a sizable income supplement. After another 4 years, we looked at children’s psychiatric symptoms before and after the “intervention.” We found that children whose families moved out of poverty had reduced Conduct Disorder symptoms, but that the intervention had little effect on depression, anxiety, or Attention-Deficit/Hyperactivity Disorder (ADHD; E. J. Costello, Compton, Keeler, & Angold, 2003). Because every man, woman, and child on the reservation received the income supplement, there was no possibility that the effect of an increased income could be confounded with the sort of qualities (hard work, thrift, etc.) that could cause both an income increase and a reduction in behavioral symptoms.

The other set of methods to deal with competing risk factors is statistical. Epidemiologists have always been careful to make it clear that nonexperimental studies can show associational but not causal relationships between risk factors and outcomes. Recently, however, they are coming closer to claiming the ability to talk about “causal associations” (J. Robins, 1997; J. Robins et al., 2000). Some have gone so far as to claim that properly designed observational studies can produce results that are superior to those based on experimental designs, because they often have a level of ecological validity that experimental studies lack (Benson & Hartz, 2000; Concato, Shah, & Horwitz, 2000; Winship & Morgan, 1999).

The idea that some effect modifiers could operate as protective factors has been widely discussed (Garmezy, 1988; Loeber, Farrington, Stouthamer-Loeber, Moffitt, & Caspi, 1998; Stouthamer-Loeber et al., 1993). As Rutter (1985) has pointed out, there are logical problems in identifying something as a protective factor, except in the presence of a risk or vulnerability; the concept of protection implies the presence of risk. However, in terms of Figure 3.1, it is reasonable to talk about protection from risk factors for a dis-

ease, as well as protection from risk of disease, given exposure. For example, decent sewage systems protect the whole community from exposure to the cholera vibrio, and good nutrition might help to protect an individual exposed to the infection from actually developing the disease.

Measuring the Impact of Risk and Protective Factors

One implication of this discussion of risk factors is that it is possible to rank risk (and protective) factors in terms of their relative importance to the rate of an observed disorder, and thus to make decisions about the most cost-efficient preventive strategies. There are several ways to calculate the importance of a factor's contribution to the prevalence of a disease. Two of these are risk ratio or relative risk and excess or attributable risk. Relative risk is a ratio comparing two risks of disease, often, the risk of a disease in a group exposed to a risk factor compared with the risk in a nonexposed group (e.g., the risk of depression in children of divorced parents compared with the risk to children in intact families). Attributable risk is an estimate of the extra cases of disease (above the rate in the nonexposed population) attributable to exposure to a particular risk factor. Attributable risk is a function of two factors: the relative risk in groups exposed and not exposed to the risk factor and the frequency of the risk factor in the population. Thus, even if the relative risk associated with a risk factor is high, the attributable risk, and thus the decrease in incidence of the disease if that risk factor were removed, may be low if the proportion of people in the population exposed to that risk factor is low. For example, there might be a high relative risk for lung cancer associated with exposure to a chemical used only in one particular industry, but the attributable risk would be low if only a few people worked in that industry and were exposed to that chemical. From a public health viewpoint, a greater reduction in the number of cases of lung cancer might be achieved by removing a risk factor with a lower relative risk but to which more people are exposed, for example, asbestos or cigarette smoke (Lilienfeld & Lilienfeld, 1980; Rothman, 1976). Measures of relative risk are particularly important for the scientific aspect of epidemiology, because they are a way of estimating the causal impact of risk factors. Measures of attributable risk are of particular interest from the practical point of view, because they can generate an estimate of the impact of a risk or protective factor in real or proportional terms.

This discussion of causality begs an underlying question: whether it makes any sense to think about human behavioral development in terms of continuity and causes. Some developmental psychologists have argued that predic-

tion is not only difficult but is unnecessary for the study of psychopathology (Lewis, 1990). Epidemiology has not adopted this approach; on the contrary, it has put its money on its ability to control disease through the prediction of causal pathways, and historically this has been an immensely successful bet. The interesting question is whether it is an approach that will prove to be as effective in the area of developmental psychopathology as it has been for infectious diseases.

Summary

In this section, we have discussed three functions of epidemiology: (1) to measure disease frequency and risk exposure; (2) to make valid generalizations from samples to populations; and (3) to control bias in relating risk factors to disease. The next question is whether, and how, the methods and ideas that have evolved over the past century, primarily to tackle infectious diseases, can be adapted to a moving target like developmental psychopathology.

WHAT IS DEVELOPMENTAL EPIDEMIOLOGY?

Epidemiology is inherently a developmental discipline, as shown in Figure 3.1, in the sense that it is concerned with the development of disease and how to intervene in that process. However, we talk about developmental epidemiology as a special variety of epidemiology when we are dealing with child psychopathology. The reason is that in this case, we have to take account of another developmental model: the model that describes the development of the individual. From this point of view, developmental epidemiology can be seen as concerned with the interaction between two developmental processes: of the organism (the child) and of the disease. The importance of understanding this interaction was pointed out by Anna Freud (1965; see Cicchetti, 1990a; Rutter, 1988), but her view of what develops was somewhat different from the view of both developmental psychology and developmental psychopathology today. In this chapter, our use of the concept of development, which follows that of developmental psychology and biology, will be familiar to developmentalists but may carry different implications for child psychiatrists and pediatricians trained to use the term development either in the context of psychodynamic theories of personality (Dare, 1985) or to refer to specific, mainly physical or cognitive, stages of development (American Psychiatric Association, 1994). For clarification, we offer a brief review of what we understand by development.

The Concept of Development

Earlier in this chapter, we discussed epidemiology as a scientific method of understanding the development of disease (see Figure 3.1). This approach shows marked similarities with the way the word development is applied to biological organisms (Hay & Angold, 1993). As Nagel (1957, p. 15) defined it:

The concept of development involves two essential components: the notion of a system possessing a definite structure and a definite set of preexisting capacities; and the notion of a sequential set of changes in the system, yielding relatively permanent but novel increments not only in its structure but in its modes of operation.

The process of disease progression has much in common with development: It is “programmed” by the nature of the transformation of the organism that begins the process, and in general it follows a reasonably regular course, although with wide variations in its rate. Furthermore, there is hierarchical integration as diseases develop. Each stage in the progress of a given disease builds on the previous stages, and many of the manifestations of earlier stages are “integrated” into later symptomatology.

This has much in common with the idea of *epigenesis*, as developed by Gottlieb (1991, p. 7):

Individual development is characterized by an increase of complexity of organization (i.e., the emergence of new structural and functional properties and competencies) at all levels of analysis (molecular, subcellular, cellular, organismic) as a consequence of horizontal and vertical coactions among the organisms’ parts, including organism-environment coactions. Horizontal coactions are those that occur at the same level (gene-gene . . . organism-organism), whereas vertical coactions occur at different levels (. . . cell-tissue . . . behavioral activity-nervous system) and are reciprocal, meaning that they can influence each other in either direction, from lower to higher or from higher to lower levels of the developing system.

For example, the genome controls cell structure, but environmentally induced cytoplasmic changes are capable of switching genes on and off (Ho, 1984; Jollos, 1934); neural differentiation in the mammalian visual cortex is dramatically affected by sensory experience (Black & Greenough, 1986); and neuroendocrine mechanisms are powerfully influenced by sociocultural factors (Mineka, Gunnar, & Champoux, 1986; Worthman, 1987; Worthman & Konner, 1987). Recent longitudinal epidemiologic studies showed that a functional polymorphism in the gene encoding the neurotransmitter-metabolizing enzyme monoamine oxidase

A (MAOA) moderated the effect of early maltreatment, so that maltreated children, if they owned the allele conferring high levels of MAOA expression, were less likely to develop antisocial problems in adolescence (Caspi et al., 2002; Foley et al., 2004). Thus, the concept of development used here (1) presupposes change and novelty, (2) underscores the importance of timing in behavioral establishment and organization, (3) emphasizes multiple determination, and (4) leads us not to expect invariant relationships between causes and outcomes across the span of development (Cacioppo & Tassinari, 1991; Cairns, 1991).

Behavior is seen as resulting from the dynamic interaction of multiple interdependent systems in both the individual and the environment. As summarized by Eisenberg (1977, p. 220), “The process of development is the crucial link between genetic determinants and environmental variables, between individual psychology and sociology.” It is characteristic of such systems that they consist of feedback and feed-forward loops of varying complexity. Organism and environment are mutually constraining, however, with the result that developmental pathways show relatively high levels of canalization (Angoff, 1988; Cairns, Garipey, & Hood, 1990; Gottlieb, 1991; Greenough, 1991; McGue, 1989; Plomin, DeFries, & Loehlin, 1977; Scarr & McCartney, 1983). For example, consider the well-established path to substance abuse (Kandel & Davies, 1982):

Beer or wine → Cigarettes or hard liquor
→ Marijuana → Other illicit drugs

It is characteristic of this pathway that the number of individuals at each level becomes smaller, but that those at the higher levels continue to show behaviors characteristic of the earlier stages. Having described such a pathway, the task is to understand the process by which it is established and to invent preventive strategies appropriate to the various stages of the developmental pathway. Such strategies must be appropriate to the developmental stage of both the individual at risk and the disorder.

Research based on this view of development has been going on for several decades, as these volumes attest, but has taken some time to influence child psychiatric epidemiology (Angold & Costello, 1991; Broidy et al., 2003; Brook, Cohen, & Jaeger, 1998; Buka & Lipsitt, 1994; E. J. Costello & Angold, 1993; Jaffee et al., 2002; Rutter, 1988). Conversely, until recently, developmental psychopathology has paid less attention to some of the key concerns of epidemiology—in particular, the importance of representative samples and controls for confounding—but this is beginning to change.

Implications of a Developmental Approach to Child Psychiatric Epidemiology

Child psychiatry, in its current manifestation in the United States, has modeled its nosology and its concepts of health and disease on adult psychiatry, using the same nomenclature and static assumptions about causality, risk factors, course, and outcome. But children are not scaled-down adults, and this approach causes serious problems for the epidemiologist concerned with explaining patterns of disease distribution in the community. Why, for example, do rates of depressive disorders, which are low in prepubertal children of both sexes, continue low in postpubertal boys but rise very sharply in postpubertal girls (Angold, Costello, & Worthman, 1999; Angold, Worthman, & Costello, 2003)? Is the increase causally associated with age, or with pubertal status, or with something else entirely? To understand these phenomena, it seems reasonable to postulate that children are organisms developing at a different rate from adults, organisms in whom developmental changes dramatically alter both the ways they can manifest their genetic endowment and the nature of their interactions with their surroundings. Here we consider the implications of some basic principles of developmental theory for the epidemiology of child psychiatric disorders.

Implication 1: Development Implies Change

This may seem to be an obvious statement, but child psychiatric epidemiology has not always taken the idea of change very seriously. This is partly the result of the current systems for the classification of diseases, which are essentially nondevelopmental. Most disorders have definitions that take no account of age or developmental level, sometimes in spite of overwhelming evidence that age-dependent changes are a central feature of the phenomenology of the disorders involved. Conduct Disorder is a good example. Loeber and colleagues (Loeber, Keenan, & Zhang, 1997) identified three different developmental pathways involving antisocial behavior. If a cross-sectional, snapshot view was taken of behavior at any point in time, children who pursued any of these three pathways shared many characteristics. Longitudinal studies, however, revealed different patterns. Children who followed the authority conflict path tended to show conduct problems early in life, to have trouble at school because of hyperactivity and learning difficulties as well as conduct problems, to explore a wide range of different deviant behaviors, and to remain deviant well into adulthood. Some of the same behaviors could be found in other children at any given time, but a second group of these followed a different, covert pathway, with a higher remission rate.

These children tended to have started showing deviant behavior later in childhood than the first group and to have had fewer problems at school or with peers. Longitudinal studies also suggested the existence of a third group who, like the first, were aggressively deviant in adolescence, but who showed little or no early Conduct Disorder. The evidence for these different developmental patterns has been pieced together from a multitude of different studies, using both clinical and population samples, and is much stronger for boys than for girls (Loeber & Baicker-McKee, 1990). The *DSM-IV*, in contrast, ignores strong evidence that Conduct Disorder in children is a precursor of Antisocial Personality Disorder in adults (L. N. Robins & Price, 1991; L. N. Robins & Wish, 1977), to the extent of coding Conduct Disorder on Axis I (Clinical Disorders) and adult Antisocial Personality Disorder on Axis II (Personality Disorders and Mental Retardation).

Questions about development and change can be addressed using methods developed to identify developmental trajectories (Land & Nagin, 1996; Nagin & Tremblay, 2001a). These methods have been used, for example, to show that there are important differences between children who show persistent, rather than time-limited, conduct problems (Foster, Nagin, Hagan, Costello, & Angold, 2005; Maughan, Pickles, Rowe, Costello, & Angold, 2000; Nagin & Tremblay, 2001b) or obesity (Mustillo et al., 2003).

Implication 2: Development Is Goal-Directed

If we accept what Mayr (1982) called the biological “metaphor” or “heuristic” of development, then we accept a teleonomic, goal-directed explanation as part of that metaphor. In Mayr’s words:

A physiological process or a behavior that owes its goal-directedness to the operation of a program can be designated as teleonomic. . . . All the processes of individual development (ontogeny) as well as all seemingly goal-directed behaviors of individuals fall in this category, and are characterized by two components: they are guided by a program, and they depend on the existence of some endpoint or goal which is foreseen in the program regulating the behavior. . . . Each particular program is the result of natural selection and is constantly adjusted by the selective value of the achieved endpoint. (p. 48)

Teleonomic activities are distinguished by Mayr from other types of teleological processes—most important, for our purposes, from those performed by adapted systems (e.g., the cardiovascular or respiratory systems) that “owe their adaptedness to a past selectionist process” (p. 49; see also Hay & Angold, 1993).

TABLE 3.1 Salient Development Issues

Age (Years)	Issues
0–1	Biological regulation; harmonious dyadic interaction; formation of an effective attachment relationship.
1–2.5	Exploration, experimentation, and mastery of the object world (caregiver as secure base); individualization and autonomy; responding to external control of impulses.
3–5	Flexible self-control; self-reliance; initiative; identification and gender concept; establishing effective peer contacts (empathy).
6–12	Social understanding (equity, fairness); gender constancy; same-sex chumships; sense of “industry” (competence); school adjustment.
13+	Formal operations (flexible perspective taking; “as if” thinking); loyal friendships (same sex); beginning heterosexual relationships; emancipation; identity.

From “The Domain of Developmental Psychopathology,” by L. A. Sroufe and M. Rutter, 1984, *Child Development*, 55, p. 22.

A teleonomic approach has particular advantages for developmental epidemiology, given its concern with disease elimination and service provision. It enables us to conceive of disease states in terms of inability to achieve one or more of the goals of development, and it points preventive efforts in the direction of those situations in which a particular process or task seems to be particularly salient at a certain phase of life. For example, Sroufe and Rutter (1984, p. 22) have outlined “a series of developmental issues . . . based on the collective experience of numerous developmentalists . . . cutting across affective, cognitive, and social domains” (reproduced in Table 3.1).

Table 3.1 has two major implications for epidemiology. First, it implies that if we want to prevent, for example, Conduct Disorder, we need to define the goal of orderly conduct and the various systems (affect, cognition, impulse, and muscular control) that are most involved with regulating conduct at different developmental stages. This means that we need research to address such questions as the following: Do children who have achieved the goal of forming secure attachments around 1 year of age find behavioral control at age 5 easier than insecurely attached children (Greenberg, Speltz, & DeKlyen, 1993; Lyons-Ruth, 1996)? Intervention designs can be used to test a hierarchical, causal relationship among the various stages (see Cicchetti, 1990b; Cicchetti & Toth, 1992, for a more detailed discussion of this point).

A second, linked implication is that pathology that looks very different at different stages may be causally linked; for example, the “anxious attachment” of a 1-year-old may be causally linked to the emotional lability and superficial friendliness of the same child at age 5, and to an inability to

form lasting intimate relationships as an adult. If this were the case, then, from a public health point of view, efforts to support secure attachments in infants would be justified, not just by the manifest anxiety of some 1-year-olds, but by the chance of preventing the social disruption caused by those same children as adolescents and adults.

Implication 3: The Goal of Development Is Normality

Normality is a state not requiring intervention: We would argue the value for developmental epidemiological research of taking the position that the goal of development is normality. That is, among the multiple outcomes of any developmental process there exists a wide range that are not likely to cause a child any serious problems in moving to the next developmental phase or task; any of these outcomes should be defined as normal. Normality and pathology in an epidemiological context can thus be defined in terms of decision making: Is some sort of intervention indicated?

In this respect, epidemiology moves along a different track from much of developmental psychopathology. The latter has tended to adopt the viewpoint of developmental psychology, that many phenomena of interest are best measured on some sort of continuous scale, representing a hypothesized underlying distribution of symptoms or capacities in the population. This makes sense for disciplines whose aim is to map out the pathways by which children’s thoughts, feelings, and actions change over time under different internal and external controls (Pickles & Angold, 2003). The specific concern of epidemiology, however, functioning as it does at the interface between scientific understanding and public health, is with those patterns of thought, feeling, and action about which “something must be done” at a given stage for the sake of the child’s present or future well-being, or in response to pressures from families, schools, or society in general. Thus, we define a developmental abnormality from an epidemiological point of view as “a state in which intervention is indicated,” and normality as “a state in which intervention is not indicated.” These definitions do not necessarily require that an intervention be available or effective, only that pathology has a social meaning as well as a medical and a developmental one, and that a corollary of defining a syndrome as pathological is that one would intervene if it were feasible. In this, public health and clinical medicine are alike.

This view of normality and abnormality requires us to take into account not only the symptom or behavior, but also the developmental stage at which it occurs, in deciding whether to devote major efforts to prevention. Taking an example from externalizing behaviors, Loeber and Le Blanc

(1990) pulled together evidence from many studies to argue that behavior that is not highly predictive of later Conduct Disorder in most children at a certain stage may be highly predictive in a specific child if (1) it first occurs earlier than in “normal” children; (2) it occurs with greater frequency than in “normal” children; and (3) it forms part of a “larger-than-normal” or more diversified symptom cluster. These developmental abnormalities frequently go together (Cohen, 1990; Farrington, 1983; Tolan, 1987). This implies that, for example, boys younger than 12 who commit minor acts of theft, vandalism, and substance abuse should be treated as showing a serious problem for which intervention is needed, whereas boys who first commit such acts after age 12 should not be treated so seriously. This is based on evidence that children who begin such acts early are likely to show a much higher rate of delinquency in their late teens than those who begin later (Fréchette & Le Blanc, 1987; Tolan, 1987) and to continue showing delinquent behavior for a longer period of time (Le Blanc & Fréchette, 1989).

Thus, the concept of goal-directed changes toward developmentally appropriate, normal behavior provides a framework within which to study patterns of pathology in time and space and links the study of human development to the study of disease under the heading of developmental epidemiology.

FROM CHILD PSYCHIATRIC EPIDEMIOLOGY TO DEVELOPMENTAL EPIDEMIOLOGY: A BRIEF HISTORY

In this section, we trace the history of developmental epidemiology from the earliest days of child psychiatry to the present.

The Origins of Child Psychiatric Epidemiology

Work on the epidemiology of child and adolescent psychiatric disorders was first undertaken in the late nineteenth century to answer the most pressing question that faced the emerging discipline of child psychiatry: how to classify and care for children with severe disabilities, many of whom were likely to be a public expense for much of their lives. In this context, the main concerns were to identify the nature of the deficits shown by severely impaired children and to find out how many of such children there were.

In the nineteenth century, the disease concept of psychiatric illness replaced the earlier view of psychiatric illness as “moral insanity” (Prichard, 1837).

Mental disease was regarded as a “thing” residing within the affected individual; cases could therefore be counted in the same way as in the epidemiology of physical disease. At the same time, reforms in the administration of psychiatric services (e.g., the assumption by the state of responsibility for mental hospitals) increased the need for statistics and paved the way for epidemiological studies. (Jablensky, 1986, p. 274)

There appear to have been few children in mental hospitals or asylums in the nineteenth century (von Gontard, 1988), but an analogous problem arose here, too: how to identify children who could never be expected to become self-sufficient adults and for whom long-term care, probably at public expense, would be needed (Grob, 1985).

Distinguishing Psychiatric Disorder from Severe Mental Retardation

An important and basic distinction to be made by the end of the nineteenth century was one between “imbeciles” and “lunatics.” As universal education spread across Europe and the United States in the second half of the century, children who could not handle the demands of the educational system became a visible and troubling group. In their historical overview of child psychiatry, Chess and Habibi (1978) pointed out that the distinction between, and division of responsibility for, “idiots” and “lunatics” was far from clear until the twentieth century; in 1876, all the charter members of the American Association on Mental Deficiency were psychiatrists, and the child guidance movement in the United States began at the University of Pennsylvania in a clinic set up by Witmer in 1894 primarily to care for the feeble-minded. Gradually, over the course of the nineteenth century, specific groups of children were described, and causes for their disabilities were identified. John Langdon Down (1867), a psychiatrist and superintendent of a large asylum for idiots, described Down syndrome, and William Ireland (1877), superintendent of the Scottish National Institution for Imbecile Children, developed a classification into such categories as epileptic, microcephalic, and inflammatory idiocy, demonstrating that the same phenomenon of idiocy could result from many different causes. Mental retardation slowly became recognized as a problem to be treated separately from behavioral and emotional problems. Children with severe developmental deficits began to be seen as lying on a continuum of disability with children who were struggling to survive the new compulsory education system, rather than as simply part of the general class of severely dysfunctional children

(although, of course, some children might have both intellectual and psychiatric problems). For example, special classes for the “feeble-minded” were mandated in England by the Elementary Education Act (Defective and Epileptic Children) of 1899. Throughout the industrialized world, as the right of all children to education was acknowledged, the care of the mentally retarded largely moved out of the sphere of psychiatry, unless emotional or behavioral problems were also severe. Causal theories focused on genetics, perinatal insults, and early environmental adversity; treatment centered on pinpointing precise deficits and maximizing children’s potential, rather than “curing” them, as the pioneers in the treatment of idiocy had hoped to do (von Gontard, 1988).

Distinguishing among Psychiatric Disorders

From the same period, descriptions can be found of children whose cognitive development was normal but who showed serious emotional or behavioral problems. In 1835, the physician James Prichard (1786–1848) wrote that “idiotism and imbecility are observed in childhood, but insanity, properly so termed, is rare before the age of puberty” (1837, p. 127). Following Pinel, the French psychiatrist who had first described “madness without delirium,” Prichard distinguished “moral insanity” from, on the one hand, “mania, or raving madness . . . in which the mind is totally deranged” (p. 16), and which he attributed to physical causes such as convulsions, and, on the other hand, imbecility or mental retardation. He thus used “moral” in its eighteenth-century sense of pertaining to personality or character. Henry Maudsley (1879), writing 30 years later, used the term in its nineteenth-century sense, referring to ethics and norms. He distinguished between instinctive insanity, which was “an aberration and exaggeration of instincts and passions,” and moral insanity, which was a defect of the moral qualities along a dimension of “viciousness to those extreme manifestations which pass far beyond what anyone would call wickedness” (p. 289). In the process, he broadened the realm of child psychiatry to include problems of conduct previously seen to be the responsibility of religion and the law. Maudsley preferred to use the term “affective” (where Prichard used “moral”) “as being a more general term and expressing more truly the fundamental condition of nerve-element, which shows itself in affections of the mode of feeling generally, not of the special mode of moral feeling only” (p. 280).

When writing about etiology rather than classification, however, Prichard and Maudsley followed the French tradition in distinguishing between moral and physical causes of

mental disorder, using moral in the sense of what came to be called exogenous causes. Prichard (1837), quoting Georget, listed among moral causes of insanity domestic grief, disappointment in love, political events, fanaticism, jealousy, poverty or reversal of fortune, reading romances, and excessive study. Mental retardation was seen as stemming exclusively from physical causes: either convulsions of some type in the early years, or some defect transmitted from the parent. This defect might itself be inherited, or it might be “traceable to parental intemperance and excess” (p. 44; see Maudsley, 1879).

The dominant causal theory of psychopathology in the second half of the nineteenth century was genetic: Heredity and degeneration caused disease, which started with scarcely perceptible signs in early childhood but took a progressive and irreversible course and would probably be transmitted to future generations if the affected individual were permitted to breed. Even when the proximal cause of insanity was a moral one, “the different forms of insanity that occur in young children . . . are almost always traceable to nervous disease in the preceding generation” (Maudsley, 1879, p. 68).

Psychiatrists in the nineteenth century thus had a developmental causal theory about psychopathology, but it was a narrow form of developmental theory: The development of the disease was progressive and irreversible, tied to the development of the child only in that it manifested itself differently as the child grew, but impervious to other influences, such as treatment or learning. “All one could do was to prevent the most extreme manifestations by strict punishment and to protect those not affected” (von Gontard, 1988, p. 579). The most effective defense for society was to prevent the procreation of the insane, and eugenics and lifelong segregation in asylums were seen as more effective intervention strategies than attempting treatment or cure. Although a continuum of severity was documented in child psychiatric disorders, as it was in mental retardation, the continuum was interpreted quite differently. It took the form of a continuum of degeneration caused by the disease within the individual across time, rather than a distribution of severity that would remain fairly constant across individuals over time, as was the case for mental retardation. Thus, the prognosis, even for children who presented with mild symptoms, was believed to be gloomy.

Psychoanalytic Theory and Developmental Psychopathology

One of the strengths of the psychoanalytic approach to psychopathology, as its theory and treatment methods de-

veloped around the turn of the twentieth century, was that it rejected the therapeutic pessimism of much contemporary child psychiatry. Although Sigmund Freud himself accepted that individuals had innate or constitutional characteristics, he developed what his daughter, Anna Freud (1965, p. 520), described as an:

etiological formula of a sliding scale of internal and external influences: that there are people whose sexual constitution would not have led them into a neurosis if they had not had [certain] experiences, and these experiences would not have had a traumatic effect on them if their libido had been otherwise disposed. (See S. Freud, 1916–1917, p. 347.)

Children whose libido “disposed” them to pathology could be saved by the right environment, or therapy, or both. Thus, although even mild symptoms could be ominous, the course was not inevitable.

Psychoanalytic theory was fundamentally developmental at a time when the term had no place in mainline child psychiatry; as an example, the entries under the heading “Development” in the index of Anna Freud’s *Normality and Pathology in Childhood* (1965) take up two columns, whereas there is not a single entry under that heading in two of the classics of mid-twentieth-century American child psychiatry (Chess & Habibi, 1978; Kanner, 1945, 1972). Psychoanalytic theory was also developmental in the multiple senses discussed in this chapter and throughout this volume: It emphasized the multiple determination of outcomes, the transformation and hierarchical integration of behavior, and the emergence of novelty. In the words of Anna Freud (1965, pp. 166–167):

As we abandon thinking in terms of specific causes of dissociality, we become able to think increasingly in terms of successful or unsuccessful transformations of the self-indulgent and asocial trends and attitudes which normally are part of the original nature of the child. This helps to construct developmental lines which lead to pathological results, although these are more complex, less well defined, and contain a wider range of possibilities than the lines of normal development.

This approach held sway over child psychiatry for almost a century, despite a lack of empirical evidence supporting its interpretation of the etiology of mental disorders (Grunbaum, 1977). In the past 2 decades, Freudian developmental psychopathology, with its emphasis on etiology, has largely been replaced, particularly in the United States, by a more phenomenological approach whose goal has been to follow the example of medicine, which looks for diseases that have a standard etiology and set of manifestations, and of some

branches of psychology, which seek to pin down concepts like intelligence in forms that are deliberately designed to transcend differences that are a function of developmental factors (Cairns & Cairns, 1991). However, although the content of psychodynamic theory has not stood up to empirical research, the form of the theory, with its emphasis on how the development of the child and of the disease are intertwined, retains considerable attraction as a model for developmental psychopathology and epidemiology.

Distinguishing Normal from Abnormal

In contrast to the earlier concentration on severe disorder, work began in the 1940s to differentiate between what Lapouse and Monk (1958) called “deviations from the usual pattern” from behavior that could be seen (at least in hindsight) to be part of the picture of normal development:

One of the great psychiatric dilemmas of our time is the decision as to what is normal and what is abnormal in human behavior. Lacking specific tests to make the distinction, the diagnostician has recourse mainly to his clinical judgment which rests on his training, experience, perceptiveness, and theoretical persuasion. In child psychiatry, Leo Kanner pointed out that recorded symptoms “are of necessity those of selected groups and not of the total population of children”; and, he continued, “This selectiveness, in the absence of ‘normal controls’ has often resulted in a tendency to attribute to single behavior items an exaggerated ‘seriousness’ with regard to their intrinsic psychopathologic significance. The seriousness becomes attached to the signal regardless of what it announces and who announces it. The high annoyance threshold of many fond and fondly resourceful parents keeps away from clinics and out of reach of statistics a multitude of early breath holders, nail biters, nose pickers and casual masturbators who, largely because of this kind of parental attitude, develop into reasonably happy and well-adjusted adults.” (Lapouse & Monk, 1958, p. 1136, quoting Kanner, 1945)

By 1970 a number of older general population studies (Cullen & Boundy, 1966; Cummings, 1944; Griffiths, 1952; Haggerty, 1925; Lapouse, 1966; Lapouse & Monk, 1958, 1964; Long, 1941; McFie, 1934; Olson, 1930; Wickman, 1928; Young-Masten, 1938; Yourman, 1932) had reported prevalences of individual problem behaviors reported by parents and teachers of older children and adolescents. One of the achievements of these early child psychiatric epidemiologists was to document just how common individual “abnormal” behaviors are in the general population of children. For example, in their survey of a random sample of 6- to 12-year-olds in Buffalo, New York, Lapouse and Monk (1958)

found that 43% of children were reported by their mother to have seven or more fears or worries, 49% to be overactive, and 48% to lose their tempers twice a week or more. Similarly, Shepherd et al. (1971) found that, on their scale of 25 “deviant” behaviors, only 40% of a population sample of elementary school children in Buckinghamshire, England, was not deviant. However, only 2.6% of the children were deviant in seven or more areas. Some of these studies (e.g., Cummings, 1944; Griffiths, 1952; Macfarlane, Allen, & Honzik, 1954) also illustrate a point that seems often to have been forgotten until recently (Loeber & Stouthamer-Loeber, 1997; Tremblay et al., 1999): that some conduct problems now associated with *DSM-IV* Conduct Disorder, such as lying and some forms of aggression, actually have their peak prevalence before age 5 rather than during adolescence.

Measuring Child and Adolescent Psychopathology

The problem with the approach to measuring the prevalence of child psychopathology used in these two studies was illuminated by a review of prevalence studies commissioned for President Carter’s Commission on Mental Illness (M. S. Gould, Wunsch-Hitzig, & Dohrenwend, 1980). Prevalence estimates of childhood psychopathology varied widely, depending on whether parents or teachers were surveyed (at that time, children were rarely asked about their own problems). Estimates of the prevalence of “maladjustment” varied widely even when they were based on data from the same informant group: from 6.6% to 22% according to teachers, and from 10.9% to 37% according to mothers. It is difficult either to plan service delivery systems or to examine causal factors if the rate of the disorder itself is so imprecise.

The questionnaires used in the 1950s and 1960s had three other disadvantages for epidemiological research: (1) They were not designed to distinguish clearly among different syndromes or diagnostic clusters of symptoms; (2) they did not take developmental changes into account; and (3) they did not, as a rule, differentiate symptoms of a disorder from any impairment in functioning that might accompany those symptoms but not be a part of the syndrome itself. For example, failing to perform at age-appropriate levels in school could be a symptom of general mental retardation, a specific learning difficulty, or attentional problems associated with ADHD or depression, or it could result from repeated absence from school because of acute separation anxiety or a chronic physical illness. General maladjustment scales did not make it easy to study the relationship between symptoms and impaired functioning in a way that might illuminate causal relationships.

Epidemiologists and clinical researchers have tackled this problem in several different ways in recent decades. The goal of all these approaches is to elicit information that will identify children with psychiatric syndromes or disorders, but the methods differ substantially. Some have developed survey-type questionnaires consisting of questions designed to mirror the symptoms described in a psychiatric taxonomy such as the *DSM* or *ICD*. Others, wanting to capture more of the detailed information about symptom severity, duration, age at onset, and associated impairment that is needed, together with symptom reports, to make a diagnosis or devise a treatment plan, have developed structured psychiatric interviews (Shaffer et al., 1999). The goal (Angold, 2002) has been to mirror as closely as possible the diagnostic skill of experienced child psychiatrists, while overcoming the twin problems that clinicians are notoriously unreliable (Zubin, 1978) and are usually too expensive to be used in large or longitudinal community studies. Here we discuss one or two issues about the use of questionnaires that have implications for developmental epidemiology; the area is covered in detail elsewhere (Angold, 2002; Shaffer et al., 1999).

Questionnaires for Assessing Child Psychopathology

There are hundreds of questionnaires designed for the child, teacher, or parent to complete, covering psychopathology in general or specific syndromes. We discuss just one set of these as examples of the strengths and weaknesses of this approach for developmental epidemiology. Achenbach and his colleagues set out to develop a set of interrelated symptom questionnaires (now called the Achenbach System of Empirically Based Assessment: ASEBA; Achenbach & Rescorla, 2000, 2001, 2003) whose items were selected using a mixture of clinical and epidemiologic methods. The original set of behavioral and emotional problems was compiled from clinical sources, but the process of reducing the list to the number finally selected was based on studies using general population samples. The first of the questionnaires, the Child Behavior Checklist (CBCL; Achenbach & Edelbrock, 1983), was designed for use by parents whose children were 4 through 16. Items endorsed by fewer than 5% or more than 95% of parents were rejected, and language was simplified to be understandable by anyone with a fourth grade education. Achenbach and Edelbrock carried out extensive factor-analytic studies of how items clustered together in children of different age groups and genders. Many of the syndromes identified in this way showed clear links to the standard diagnostic labels used in psychiatry (Verhulst, van der Ende, Ferdinand, & Kasius, 1997). This is not surprising, as the original set of items

was submitted by clinicians familiar with how children's symptoms tend to present. However, the CBCL proved to have much higher test-retest reliability than clinicians did and was quick to administer and score.

The work of Achenbach and his colleagues has provided some powerful tools for developmental epidemiology, both practically and conceptually. First, the extensive data collection and careful standardization on large samples set high standards for instrument development. Second, the team developed a closely integrated set of scales associated with the original CBCL, covering infancy to adulthood and available in versions for parent, teacher, and self-report. Third, the list of emotional and behavioral problems is set in the context of questions about the child's social competencies and school performance; basic sociodemographic information also is collected. Fourth, a lot of work has gone into language and layout, and the 4-page questionnaires collect a great deal of information in a brief time (about 20 minutes). As a result of these virtues, the instruments are very widely used for both clinical and epidemiological purposes. They have been translated into many languages, encouraging cross-cultural studies of the generalizability of the identified symptoms and syndromes and their correlates (e.g., van Eldik, Treffers, Veerman, & Verhulst, 2004; Verhulst, Achenbach, Althaus, & Akkerhuis, 1988; Weisz, 1989).

The many virtues of the questionnaire approach adopted by Achenbach and colleagues make it all the more important to recognize its limitations (Achenbach, 1985). First, the strategy of omitting rarely endorsed symptoms means that this method cannot be used to describe some of the most severe and disabling problems, for example, those seen in autistic children. Second, it is important to note that the questionnaire method is predicated on the assumption that the respondent knows the child well enough to be able to make ratings on items like "Feels too guilty" or "Lying or cheating." A checklist is thus a very well-designed form for recording information about a child that the respondent already knows, but the data that it provides can only be as good as the respondent's knowledge of the child in question. Third, this method produces a series of scale scores for each child, standardized relative to a population sample matched for age, sex, and social class. These scores cannot be used to answer such public health questions as "How many children need treatment?," unless certain decision rules are applied to them. A "clinical cut point" has been identified for the global behavioral problem score of the ASEBA checklists, based on a comparison of the scores of children referred for mental health services during the previous year with the scores of nonreferred children (Achen-

bach, 1991). However, as we discuss later, there is reliable evidence from national data and community surveys that fewer than 5% of children are receiving mental health treatment at any time, despite similarly strong evidence that three to five times as many have a psychiatric problem that entails significantly impaired functioning. Receipt of services is a poor criterion for defining need for services (Burns et al., 1995; E. J. Costello, Burns, Angold, & Leaf, 1993; E. J. Costello, Pescosolido, Angold, & Burns, 1998). It is also worth emphasizing that scale scores are standardized to identify a priori a certain percentage of the population as being in the clinical range. Thus, they cannot be used to provide prevalence estimates.

Interviews for Identifying Psychiatric Disorders in Children and Adolescents

The checklist approach does not provide the detailed information about symptom severity, duration, age at onset, and associated impairment that is needed, together with symptom reports, to make a diagnosis or devise a treatment plan. Alternative approaches are needed, ones more closely related to the process of clinical decision making. Beginning with the work of Michael Rutter in the 1960s, a large number of structured psychiatric interviews have been developed. They have much in common. All structured interviews aim to:

- Structure information coverage, so that all interviewers will have collected all relevant information (both confirmatory and disconfirmatory) from all subjects.
- Define how relevant information is to be collected.
- Structure the process by which relevant information is combined to produce a final diagnosis.

Interviews vary widely in how they go about these tasks. However, a general distinction can be made between Interviewer-based (or investigator-based) interviews, respondent-based interviews, and best estimate interviews.

Interviewer-Based Interviews. These are interviews that require the interviewer to make an informed decision based on what the respondent says. Interviewers are expected to question until they can decide whether a symptom meeting the definitions provided by the interview (or known to them from their training) is present or absent. This group of interviews includes the Anxiety Disorders Interview Schedule (Silverman & Rabian, 1995), the Child and Adolescent Psychiatric Assessment (CAPA; Angold & Costello, 2000), the Child Assessment Schedule (Hodges,

1993; Hodges et al., 1982), the paper-and-pencil (not the computerized) versions of the Diagnostic Interview Schedule for Children and Adolescents (DICA; Reich, 2000) and its close relative the Missouri Assessment of Genetics Interview for Children, the Interview Schedule for Children and Adolescents (Sherrill & Kovacs, 2000), various versions of the Kiddie Schedule for Affective Disorders and Schizophrenia (K-SADS; Ambrosini, 2000), and the Pictorial Instrument for Children and Adolescents (Ernst, Cookus, & Moravec, 2000).

Three of these interviewer-based interviews (the K-SADS-P IVR, the DICA, and the CAPA) provide extensive sets of definitions of symptoms and/or detailed guidance on the conduct of the interview. Such glossaries are particularly important when an interviewer-based interview is to be used by nonclinician interviewers because they provide detailed guidance as to what the interviewer is supposed to be looking for in making symptom ratings. Nonclinician interviewers have been shown to be able to make such “clinical” judgments with high reliability when they have received adequate training with such glossaries (Angold & Costello, 1995).

Respondent-Based Interviews. In other psychiatric interviews, it is the respondent who makes the final decision about whether a symptom is present, typically by answering yes or no to each question. The interviewer makes no such decisions, but simply reads the questions. Because the decision as to the presence or absence of psychopathology lies with the respondent in such interviews, we refer to them as respondent-based. The Diagnostic Interview Schedule for Children (DISC; Shaffer et al., 2000), the computer-assisted version of the DICA (Reich, 2000), and the Dominic-R (Valla, Bergeron, & Smolla, 2000) are the three representatives of this approach.

A variant on these two approaches to interviewing is taken in the Development and Well-Being Assessment (Goodman, Ford, Richards, Gatward, & Meltzer, 2000), which is widely used around the world. Here the interviewer uses a respondent-based approach first, then supplements the information by asking additional questions. The responses to these are integrated with the structured responses by an experienced clinician, who formulates the diagnosis.

The distinction between interviewer- and respondent-based interviews is not hard and fast in actual practice, because there has been considerable cross-fertilization between these approaches. For instance, CAPA, which has its roots in the interviewer-based tradition, includes a subset of questions that are to be asked verbatim of all subjects, as in a respondent-based interview, but then allows further questioning for clarification. On the other hand, the DICA,

which had previously been a respondent-based interview, now requires interviewers to question much more flexibly, and is currently an interviewer-based instrument (Reich, 2000). Although the distinction between interviewer- and respondent-based interviews provides a useful rough-and-ready typology, it is really better to consider interviews as lying at various locations along three dimensions: (1) degree of specification of questions, (2) degree of definition of symptom concepts, and (3) degree of flexibility in questioning permitted to the interviewers (Angold, 2002).

Summary

In this section, our goal has been to see where developmental epidemiology came from and how it got to be where it is today. The problems that had to be formulated and solved were of two kinds: how to conceive of the nature of childhood psychopathology and how to measure it. Progress in the past century has been extraordinary in both areas. However, as we discuss later, this progress has brought developmental epidemiology to a point where radically new concepts, and new methods, are now needed. Before we get there, however, we look at how epidemiologists in other areas of medicine have thought about developmental questions, and give some examples from psychiatry.

EPIDEMIOLOGY AS A DEVELOPMENTAL METHOD

Much of this section is inspired by Breslow and Day's (1980, 1987) two-volume *Statistical Methods in Cancer Research*. As those authors point out:

Most chronic diseases are the result of a process extending over decades, and many of the events occurring in this period play a substantial role. (1987, p. 2)

In the study of physical growth, of mental and hormonal development, and in the process of aging, the essential feature is that changes over time are followed at the individual level. Longitudinal surveillance and recording of these events is therefore a natural mode of study to obtain a complete picture of disease causation.

Many psychiatric disorders fall into the category of chronic diseases, and the methods developed by cancer and cardiovascular epidemiologists to explore causal relationships in such diseases can, we believe, provide at least a useful starting place for thinking about psychiatric disorders.

Chronic disease epidemiologists view the diseases they study as having inherent developmental processes of their own—processes that obey certain laws and follow certain stages even as they destroy the individual in whom they develop (Hay & Angold, 1993). Developmental epidemiology asks what happens when developmental processes embodied in pathogenesis collide with the process of human development.

Risk, Exposure, and the Meaning of Time

Many questions can be answered only by methods that take into account temporal characteristics of risk factors, including their onset and the “dose,” or level of exposure, over time. Age at first exposure, time since first exposure, duration of exposure, and intensity of exposure are all interrelated aspects of timing that may have different implications for causality and thus for prevention. The kinds of questions we are thinking of include the following:

- Does physical abuse by parental figures cause psychiatric disorders in children? Is a single blow a sufficient cause, or does abuse have to go on for a period of time, or happen at a certain level of severity, before it constitutes a risk factor? Are children of different ages or developmental stages differentially vulnerable to physical abuse as a risk factor? What risks are associated with removing children of different ages from home because of physical abuse?
- Why are depressive disorders rare in both prepubertal girls and boys, but much more common in postpubertal girls? What causes the observed sex difference to develop? Is it associated with hormonal, morphological, or social changes occurring around puberty? Why is earlier-than-average maturation apparently a positive event for boys but a negative one, associated with increased risk of behavioral and school problems, for girls?

A risk factor may have a different impact on the risk of disease, depending on when it first occurs, how long it is present, and the level of intensity at which it occurs. For example, insulation workers exposed to asbestos had a cumulative risk of dying of mesothelioma over a 20-year period (controlling for other causes of death) that was the same irrespective of age at first exposure (Peto, Seidman, & Selikoff, 1982). Here, *length of exposure* was the critical aspect of risk. In contrast, the risk of breast cancer following irradiation appears to be highest in girls exposed at ages 0 through 9, falling with age until there is little excess

risk for breast cancer associated with exposure to radiation after age 40 (Howe, 1982). Cases of breast cancer attributable to irradiation begin to occur some 10 years after exposure and continue thereafter at a roughly constant level, suggesting that the absolute excess risk increases with time since exposure. Thus, *timing of exposure* is the critical aspect of the risk exposure.

However, different sorts of radiation can have different durations as risk factors for cancer; for example, bone sarcomas occurring after exposure to the radioisotope ²²⁴Ra, which has a half-life of 3.6 days, cluster in a period of 5 to 10 years following first exposure, whereas bone sarcomas following exposure to ²²⁶Ra, which has a half-life of 1,600 years, occur at a constant rate beginning 5 years after first exposure (Mays & Spiess, 1984). In the latter case, exposure to the decay products of the radioisotope continues at virtually constant levels after absorption of the radium.

A longitudinal study of British male doctors' smoking provides an example of dose-related risk: The annual death rate per 100,000 men, between 1951 and 1971, standardized for age, was 1,317 for nonsmokers, 1,518 for those currently smoking 1 to 14 cigarettes a day, 1,829 for those currently smoking 15 to 24 a day, and 2,452 for those smoking over 24 a day (Doll & Peto, 1976). This was true irrespective of age, and risk fell quite rapidly in those who gave up smoking (Breslow & Day, 1987). In this case, *amount of exposure* was the critical factor.

Examples from Developmental Psychopathology

These examples illustrate the importance for developmental epidemiology of thinking about different aspects of development: age at first exposure, time since first exposure, duration of exposure, intensity of exposure. Here we present some examples of how child psychiatric researchers have used ingenious designs to tease out the same issues.

The importance of *age at first exposure* has been studied most intensively of all the aspects of risk over time in child psychopathology because of the theoretical importance attached to early experiences in the Freudian and other psychodynamic models of development. For example, researchers investigating the role of attachment in children's development have concentrated on the very early months and years of life as the crucial period during which the inability to form one or more such relationships may have damaging effects that last into childhood and perhaps even into adulthood (Sroufe, 1988). The critical date of onset of risk appears to occur after 6 months, but the duration of the risk period is not yet clear. (Hay, 1985; Hay, Pawlby, Angold, Harold, & Sharp, 2003) has

presented evidence that maternal depression, which presumably interferes with mothers' ability to form normal relationships with their infants, affects motor development if it occurs during the 1st year of life, and language development but not motor development if it occurs during the 2nd year of life. This is a case where age at first exposure appears to interact with the developmental processes most salient at a particular age. In another example of the importance of timing, Rutter (1985) has pointed out that once children have achieved urinary continence at around age 2, there is a period of risk for relapse into incontinence that appears to coincide with starting school. Once this period of risk is over, the chance of developing enuresis is very slight. In this case, age at exposure is clearly the critical developmental risk factor because no parallel increase in functional enuresis occurs at later times of stress, such as moving to middle or high school, and there is no delay between the stress and the symptoms.

Timing of exposure has rarely been treated separately in studies of child psychopathology. G. W. Brown and Harris (1978), in their work on the social origins of depression, argued that women who lost their mother in the 1st decade of life were more vulnerable as adults to depressive episodes in the face of severe life events. However, theirs was a retrospective study that did not address the question of whether these women were also at greater risk of depressive episodes during later childhood and adolescence. It is not clear whether the crucial factor was the length of time since exposure to the risk factor of mother's death, or the age of the child at the time of exposure, or some combination of the two.

Timing of puberty has emerged as an important aspect of risk in relation to both depression and behavioral problems. In a longitudinal study that measured not only age at menarche but also morphological development, Tanner staging (Marshall & Tanner, 1969), and levels of gonadal and steroidal hormones, it was clear that it was high levels of estrogen and testosterone, not timing of puberty, that predicted adolescent depression (Angold et al., 1999). On the other hand, there are many studies showing that girls who are early in developing the morphological signs of puberty, indexed by Tanner stage or menarche, are at risk for behavioral problems if they have unsupportive families (Ge, Brody, Conger, & Murry, 2002; Ge, Conger, & Elder, 1996; Magnusson, Stattin, & Allen, 1985; Moffitt et al., 1992).

Duration of exposure to poverty was examined by Oford and colleagues (1992) in their repeated surveys of a representative sample of children in Ontario. They showed that children whose families were living below the poverty

level at two measurement points were at increased risk of behavioral disorders, compared with children whose families were below the poverty level on one occasion only, or never. In a longitudinal study from Dunedin, New Zealand, Moffitt (1990) found that children identified at age 13 as both delinquent and hyperactive had experienced significantly more family adversity (poverty, poor maternal education and mental health), consistently from the age of 7, than children who were only delinquent or only hyperactive at age 13:

The most striking increase in the antisocial behavior of ADD+delinquent boys [diagnosed at age 13] occurred between the ages of 5 and 7, when they attained a mean antisocial rating that was not reached by other delinquent boys until 6 years later. School entry and reading failure coincided temporally with this exacerbation of antisocial behavior. These data suggest that the problem behavior of this group, despite being generally persistent, is responsive to experience. The data also reveal a key point of vulnerability that could be a target for intervention: reading readiness. (p. 906)

Another example comes from the Great Smoky Mountains Study. Children who had been assessed over an 8-year period were classified into four groups on the basis of their body-mass index (a ratio of weight to height) at each assessment: no obesity (72.8%), childhood-only obesity (5.1%), adolescent-only obesity (7.5%), and chronic obesity (14.8%). Only the chronically obese group was at increased risk of psychiatric disorder (Mustillo et al., 2003). This is an example of duration of exposure as the key risk characteristic. It is also an example of the impact of intensity of exposure, because no effects were found of overweight that fell below the threshold of obesity.

Intensity of exposure to lead (Needleman & Bellinger, 1991) provides an example of a definite dose-response relationship. Another aspect of intensity is the number of different risk factors to which a child is exposed (Seifer, Sameroff, Baldwin, & Baldwin, 1989). Rutter (1985) and others have pointed out that children exposed to one risk factor are at increased risk of exposure to others (e.g., no father in the home and poverty), and that the dose-response relationship to an increasing number of different risk factors is not a simple linear one. Most children appear to be able to cope with a single adverse circumstance, but rates of psychopathology rise sharply in children exposed to several adverse circumstances or events (Seifer et al., 1989).

These examples show that it is possible to design studies that at least begin to allow us to tease out the respective roles played by time since first exposure, age or develop-

mental stage at first exposure, duration of exposure, and intensity of exposure. Multistage models of risk, which have been developed to address the complexities of causality in chronic disease, are one way of putting the pieces together. Several such models have been proposed, particularly in the context of carcinogenesis (Peto, 1984), and have been reviewed in terms of developmental psychopathology by Pickles (1993). Statistical techniques for exploring causality in such multistage models have made great strides recently (J. Robins, 1997). The challenge is to incorporate all the various aspects of risk into a single model and distinguish the ones that carry the tune from those that are just noise.

CONCLUSIONS AND FUTURE DIRECTIONS: DEVELOPMENTAL EPIDEMIOLOGY

We have described how child psychiatric epidemiology has developed over the past 50 years as a collaborative activity of basic, clinical, and public health scientists working together to understand the magnitude of the problem of child mental illness and to identify key risk factors. Many of the fundamental problems of conceptualization and measurement have been solved, or at least reduced to manageable proportions.

Up to this point, the role of epidemiology has been mainly a descriptive one, addressing the basic questions How many? Who? Where? When? We are now in the position of being at least as capable of answering these questions reliably and accurately in child psychiatry as are chronic disease epidemiologists in other areas of medicine.

However, child psychiatry is changing, and epidemiology will change as well. The goal is now to understand how risk exposure and vulnerability change over the life course, and how the requirements of “normal” development at each developmental stage shape the types of psychopathology that emerge if these requirements are not met. The term “developmental epidemiology,” first coined by Kellam in the 1970s (Kellam, Ensminger, & Turner, 1977), is useful to describe what epidemiology is doing these days.

In this concluding section, we describe some rapidly growing research areas that will contribute to the next generation of studies to the shift from child psychiatric epidemiology to developmental epidemiology. The different approaches overlap in many areas, but we discuss the future under seven headings: longitudinal research, genetic epidemiology, life course epidemiology, intergenerational epidemiology, prevention science, studies of burden and cost, and surveillance studies.

Longitudinal Research

Longitudinal research is almost the sine qua non for testing developmental hypotheses about causes and risks. Although there have been many longitudinal developmental studies, some of them beginning at birth (or even before), longitudinal studies of psychiatric disorders had to await the development of appropriate technology, specifically, data collection methods that validly and reliably translated the psychiatric taxonomy into instruments that could be used repeatedly with the same subjects (see earlier discussion).

Table 3.2 lists some current studies with data that can be used to address issues in developmental epidemiology. The criteria used for selecting these studies were that they had (1) a representative population-based sample, (2) data collection beginning in childhood and continuing at least into adolescence, (3) at least two waves of assessment on the same subjects, and (4) data that could be used to make *DSM* or *ICD* diagnoses on all subjects in at least one data wave. (Several other studies have done psychiatric assessments on a subset of participants to evaluate their use of questionnaire measures elsewhere in the study. These do not provide a very solid basis for estimating prevalence or diagnostic continuity and so are omitted from this list.)

An example of how longitudinal studies can be used to address developmental questions can be found in a recent paper on the Great Smoky Mountains Study (E. J. Costello, Mustillo, Erkanli, Keeler, & Angold, 2003). Annual interviews with 1,420 young people over a period from age 9 through 16 provided data to address such questions as the following: Does the prevalence of different disorders increase or decrease with age? Do children with a disorder continue to have the same disorder (homotypic continuity) or a different disorder (heterotypic continuity)?

Longitudinal analyses showed that, although the average annual prevalence of psychiatric disorder was around 13%, over the period of the study more than one child in three (36.7%) had one or more disorders. Some disorders (ADHD, separation anxiety, functional enuresis) dominated the picture in childhood but had almost disappeared by age 16. Depression and drug abuse were predominantly disorders of adolescence. Anxiety disorders in general had a U-shaped distribution, falling to their lowest point at age 12. Although wave-to-wave continuity was not very high, over the course of the study there was a high degree of homotypic continuity (see Table 3.3 on p. 63). The increased likelihood of an episode of a disorder following an earlier episode was statistically significant for every diagnosis except specific phobia.

TABLE 3.2 Summary of Ongoing Longitudinal Epidemiologic Studies of Child and Adolescent Psychiatric Disorders

Adapted from "Prevalence and Development of Psychiatric Disorders in Childhood and Adolescence," by E. J. Costello, S. Mustillo, A. Erkanli, G. Keeler, and A. Angold, 2003, *Archives of General Psychiatry*, 60, pp. 837–844.

In contrast, there was relatively little prediction from one disorder to another (heterotypic continuity), and it was almost entirely restricted to girls. Anxiety predicted depression, and depression predicted anxiety. Anxiety and Conduct Disorder predicted substance abuse, and there was some movement among the disruptive behavior disorders, perhaps suggesting that the *DSM* taxonomy fits boys better than it does girls.

There are now several research groups that have used their longitudinal data to look at continuities and discontinuities in mental illness from childhood into adolescence and beyond. Some of the longitudinal studies have followed their subjects into adulthood (Caspi, Moffitt, Newman, & Silva, 1996; Cohen, 1996; Fergusson & Woodward, 2000; Reinherz, Giaconia, Hauf, Wasserman, & Silverman, 1999; Rohde, Lewinsohn, Kahler, Seeley, & Brown, 2001). These

are beginning to show indications of continuity between temperamental characteristics in early childhood and the onset of psychiatric disorders in late adolescence and young adulthood (Caspi et al., 1996; Cohen, 1996). Two examples come from the Dunedin study, a birth cohort of around 1,000 children from New Zealand who have been evaluated every 2 years since birth.

The first set of analyses (Jaffee et al., 2002) started from hints in the literature that juvenile-onset Major Depressive Disorder (MDD) may be etiologically distinct from adult-onset MDD. In these analyses, early childhood risk factors covered the period from birth to age 9 years. Diagnoses of MDD were made according to *DSM* criteria at three points prior to adulthood (ages 11, 13, and 15 years) and three points during adulthood (ages 18, 21, and 26 years). Four groups were defined: individuals first diagnosed as having

MDD in childhood, but not in adulthood ($n = 21$); individuals first diagnosed as having MDD in adulthood ($n = 314$); individuals first diagnosed in childhood whose depression recurred in adulthood by age 26 years ($n = 34$); and never-depressed individuals ($n = 629$). The two juvenile-onset groups had similar high-risk profiles on the childhood measures. Compared with the adult-depressed group, the juvenile-onset groups experienced more perinatal insults and motor skills deficits, more caretaker instability, criminality, and psychopathology in their family of origin, and more behavioral and socioemotional problems. The adult-onset group's risk profile was similar to that of the never-depressed group with the exception of elevated childhood sexual abuse. These analyses made it clear that the distinction between juvenile- versus adult-onset MDD is important for understanding heterogeneity in depression.

A second example from the same study revisited the theory that there are two types of adolescent delinquency, childhood-onset and adolescence-limited, that their manifestations in adolescence are indistinguishable, but that their consequences for persistence into adulthood are different (Moffitt, 1993). At the 26-year follow-up (Moffitt, Caspi, Harrington, & Milne, 2002), the childhood-onset delinquents were the most elevated on psychopathic personality traits, mental health problems, substance dependence, numbers of children, financial problems, work problems, and drug-related and violent crime, including violence against women and children. The adolescent-onset delinquents were less extreme at 26 years but showed elevated impulsive personality traits, mental health problems, substance dependence, financial problems, and property offenses. A third group of men who had been aggressive as children but not very delinquent as adolescents emerged as low-level chronic offenders who were anxious, depressed, and socially isolated and had financial and work problems.

These two examples serve to show how, as developmental epidemiology grows up, it can contribute to developmental psychopathology and also shine new light on some of the accepted verities of adult psychiatry.

A next step in the use of descriptive longitudinal studies for developmental epidemiology needs to be to combine them in programs of joint analyses or meta-analysis. For example, the National Institute on Drug Abuse recently funded a consortium of eight groups with longitudinal data to pool their thinking about the psychiatric precursors of adolescent drug use and abuse. This group is developing new methods for the meta-analysis of longitudinal data sets that could be used in the future to look at many other areas of developmental psychopathology. More standardized diagnostic methods make this sort of collaboration feasible.

A second goal for the future must be to work out ways of releasing data from these studies for public access so that future researchers can take advantage of these incredibly valuable resources. There are many issues to be worked out, not the least of them the protection of participants' privacy and the rights of the scientists who labored for so many years to collect the data. But these are soluble problems, and the benefits of bringing fresh minds to bear on issues in developmental epidemiology are likely to be tremendous.

Genetic Epidemiology

There have been two revolutions in genetic epidemiology in the past 2 decades that will have a tremendous impact on developmental psychopathology in the next decade.

Psychiatric Behavioral Genetics

The first revolution occurred when the methods of psychiatric epidemiology were applied to behavioral genetics. Psychiatric interviews like those described earlier were used in studies with genetically informative designs, such as twin, adoption, family, and migrant studies. For the first time, researchers explored not only the genetics of scalar characteristics, such as intelligence, but also of categorical disorders such as depression, measured in ways that approximate clinical diagnosis. Furthermore, behavioral geneticists began to take seriously issues of sampling, so that they could talk about the contribution of genes to disease in the population as a whole, rather than in highly selected families or groups. There have also been some longitudinal studies looking at how genes can have different effects at different developmental stages (Eaves & Silberg, 2003; Jacobson, Prescott, & Kendler, 2002; Lesch, 2002).

An important example of this approach is the work emerging from the Virginia Twin Study of Adolescent Behavioral Development (VTSABD), a population-based sample of twin pairs followed through adolescence into adulthood. One set of analyses investigated the role of genetic and environmental factors in the association between depressive symptoms and symptoms of Overanxious Disorder (OAD), simple phobias, and separation anxiety in 8- to 13-year-old and 14- to 17-year-old girls (Silberg, Rutter, & Eaves, 2001). There were distinct patterns underlying the association between depression and the different anxiety syndromes during the course of development. First, specific genetic influences on depression after age 14 reflected liability to symptoms of earlier OAD and simple phobias. Second, aspects of the shared environment that influenced symptoms of depression before age 14 contributed to symp-

toms of separation anxiety and simple phobias later in adolescence. Third, the shared environmental influence on depression in older girls also affected liability to symptoms of concurrent OAD and persistent separation anxiety. These results suggest that depression before and after age 14 may be etiologically distinct syndromes. Earlier symptoms of OAD and, to a lesser extent, phobic symptoms reflect the same genetic risk, and separation anxiety symptoms both before and after age 14 reflect the same environmental risk that influence liability to depressive symptoms expressed in middle to late adolescence.

Molecular Genetics

The second genetic revolution occurred when it became feasible to apply the methods of molecular genetics to epidemiologic samples. This development opens up the opportunity to use not only twin or adoption studies but a wide range of samples to test theories about candidate genes for specific symptoms. Even more exciting is the new opportunity to use the treasure-house of data from longitudinal studies to test for gene-environment interactions. Such studies can answer questions about which genes interact with which environmental factors, at what developmental stage. Two examples provide first glimpses of what is likely to be one of the most fruitful areas of developmental epidemiology in the next decade.

Investigators studied the male children from the Dunedin longitudinal study sample (Caspi et al., 2002) from birth to adulthood to determine why some children who are maltreated grow up to develop antisocial behavior, whereas others do not. A functional polymorphism in the gene encoding the neurotransmitter-metabolizing enzyme monoamine oxidase A (MAOA) was found to moderate the effect of maltreatment. Maltreated children with a genotype conferring high levels of MAOA expression were less likely to develop antisocial problems. These findings provide epidemiological evidence that genotypes can moderate children's sensitivity to environmental insults. The finding has since been replicated in the VTSABD (Foley et al., 2004).

In other analyses, the Dunedin team investigated why stressful experiences lead to depression in some people but not in others (Caspi et al., 2003). A functional polymorphism in the promoter region of the serotonin transporter (5-HTT) gene was found to moderate the influence of stressful life events on depression. Individuals with one or two copies of the short allele of the 5-HTT promoter polymorphism exhibited more depressive symptoms, diagnosable depression, and suicidality in relation to stressful life events than individuals homozygous for the long allele. Again, an individual's response to environmental insults is

moderated by his or her genetic makeup. This finding has recently been replicated (Kendler, Kuhn, & Prescott, 2004).

Geneticists have for generations been telling us that genes express themselves only in an environment, and that the key questions have to do with the relationships between the two over time. Developmental epidemiology and genetic epidemiology are already merging, and the process will continue in the next decade.

In the future, no epidemiologic study will fail to collect biomaterial for DNA and to ask participants to consent to the collection of biomaterial for DNA. In the immediate future, existing studies are going back and obtaining blood or cheek scrapes, or asking participants to consent to a new use of already collected biodata. Collaboration between molecular geneticists and epidemiologists with longitudinal data on representative samples offers an amazing opportunity for progress in understanding the biological and social origins of disease.

Life Course Epidemiology

Life course epidemiology is the study of long-term effects on chronic disease risk of physical and social exposures during gestation, childhood, adolescence, young adulthood, and later adult life. It includes studies of the biological, behavioral, and psychosocial pathways that operate across an individual's life course, as well as across generations, to influence the development of chronic diseases (Ben-Shlomo & Kuh, 2002; Kuh & Ben-Shlomo, 1997).

Psychiatric disorders are increasingly showing themselves to be chronic diseases. For example, across childhood and adolescence, for every psychiatric disorder except specific phobias, the likelihood of an episode has been shown to be significantly higher in youth with a history of the same disorder than in those with no previous history (E. J. Costello, Mustillo, et al., 2003). As data accumulate from prospective studies, it is becoming clear that the onset of most adult psychiatric disorders lies much further back in childhood than had been suspected from adult studies relying on retrospective recall of onset (Kim-Cohen et al., 2003).

In many ways, life course and developmental epidemiology mirror one another. Life course epidemiology, however, has taken on a special concern with the "embodiment" of social phenomena into the biological (Krieger, 2001), encapsulated in the concept of "health inequalities." This concern arose historically from work showing that mortality from many diseases is spread unequally across the population (Wilkinson, 1994) and that these differences in risk can be linked to social inequalities that often go back to infancy or even to the parental generation

(e.g., Barker, 1998; Davey Smith, Gunnell, & Ben-Shlomo, 2000; Leon, 2000). This body of work has had enormous significance for international thinking about social policy and is having a direct effect on the allocation of public resources in some countries.

Developmental epidemiology needs to take on board the social, economic, and political implications of the fact that children are born with different levels of risk for psychiatric disorder, that their family's socioeconomic status is part of the predictive equation, and that community-level interventions (E. J. Costello, Compton, et al., 2003), as well as individual treatment can influence how well individuals are able to function. Future studies will include health disparities (in the broad sense of medical and psychiatric health) as part of their remit.

Intergenerational Epidemiology

A life course approach to developmental epidemiology is not limited to individuals in a single generation, but can intertwine biological and social transmission of risk across generations, recognizing that geographic and secular characteristics may be unique to that cohort of individuals (Cairns, Elder, & Costello, 1996; Stein, Susser, Saenger, & Marolla, 1975).

Experiences of the previous generation can operate at many different levels of generality. They may be specific to the mother-child dyad (e.g., the effect of drug use during pregnancy) or may affect everyone living in a certain neighborhood (e.g., poverty or exposure to an environmental toxin). All mothers and children may be affected by a particular event, such as a period of famine or disease, or children may be affected by their mother's developmental stage (e.g., children of teen mothers or elderly mothers).

Models for intergenerational research have recently developed (Cairns et al., 1996; Friedman & Haywood, 1994; Rossi, 1989), and statistical methods have become more tractable (Muthen & Muthen, 2000; L. N. Robins, 1992; Zeger & Liang, 1992). Undertaking transgenerational studies requires a level of commitment from both researchers and funding agencies that is hard to sustain over the necessary length of time, especially in the United States with its 5-year funding cycles. Many American researchers have looked abroad to find countries that have nurtured such studies and governments that understand their importance (e.g., Chasiotis, Scheffer, Restemeier, & Keller, 1998; Granger et al., 1998; Krueger et al., 1998). However, we can hope that as policymakers become more aware of the overlapping pattern of risk factors among chronic diseases and the risks associated with very early exposures, they

will come to understand the immense returns from investment in multigenerational research.

Prevention Science

The strongest test of a developmental theory about causes of disease is an intervention that manipulates a core etiological factor and tests the outcome. Prevention science is the discipline that has arisen to put this principle into practice. Its strongest growth has been in the area of AIDS prevention, but it has also been an important force in developmental psychopathology, with its own academic societies and research journals.

Prevention science uses theory about the causes of disease to generate interventions, which when tested provide information not only about the effectiveness of the intervention, but also about the etiology of the disease (Dodge, 2001). The famous Broad Street pump intervention described earlier (Snow, 1855) is a classic example of prevention science: If dirty water caused cholera, then removing access to dirty water should both prevent new cases and support the etiologic hypothesis.

As described earlier, epidemiology traditionally divides prevention into three categories, depending on the mean level of risk in the population of concern. Primary prevention programs like clean water, car seat belts, and parental leave programs are examples of primary or universal prevention. The scientific questions at this level have to do with what is prevented downstream by universal programs upstream. For example, the "Just Say No" drug abstinence program was introduced as a primary prevention for all children in school, designed to stop drug use before it began. Unfortunately, the developmental science behind it was inadequate, and the results were null if not negative (Lynam et al., 1999). In another careful study of a primary prevention program for school-age children, Stattin and colleagues (Mahoney & Stattin, 2000) evaluated the youth recreation centers that are a ubiquitous feature of Swedish towns. Usually, these are places where young people can hang out, with very little adult supervision or structured activity. Participation in activities with low structure was associated with high levels of antisocial behavior for boys and girls, whereas participation in highly structured leisure activities was linked to low levels of antisocial behavior. Despite several studies, however, community leaders still strongly support these recreation centers: an example of how long it takes for research to influence policy.

On the other hand, primary prevention with both children (Kellam, Koretz, & Moscicki, 1999) and families (E. J. Costello, Compton, et al., 2003) can be effective and

suggest etiologic pathways that could be explored in further research. But prevention science has done relatively little in the way of *primary* prevention for mental health problems. It is highly likely that primary prevention programs that improve early nutrition or provide more family leave have effects on the development of psychopathology, but they have not been treated as scientific tests of theory, and so we do not know.

Secondary, or high-risk, intervention programs are much more likely to be subjected to scientifically informative testing, and this is where the bulk of prevention science has been done. There is a large number of interventions based on high-risk children, schools, and communities, and many of them have survived the trial by fire of National Institutes of Health review committees and are both theory-driven and scientifically sound. This is not the place to review this literature; the main issue for developmental epidemiology is that such studies should be epidemiologically sound. This means that it should be clear how far their results can be generalized. Does an intervention to reduce bullying (Olweus, 1993) work with girls as well as boys? In which age groups? In which ethnic groups? What can we learn about what drives bullying?

A good example of a secondary intervention that yields insights for developmental epidemiology is the "Fast Track" program for aggressive children in grade school. This was based on clearly articulated theory about cognitive difficulties that could interact with environmental risk to produce aggressive behavior in socially ambiguous situations (Dodge, Pettit, & Bates, 1994). Hostile attributional bias was indeed found to be a partial mediator of the effect of the intervention on reductions in aggressive behavior.

Tertiary interventions have hardly been explored in the context of tests of developmental theory. Once children have developed clinically defined psychiatric disorders, interventions focus on clinical treatment rather than tertiary prevention, although pediatricians (Kendrick, 1999), psychologists (Williams, Holmbeck, & Greenley, 2002), and psychiatrists (Pols et al., 1996) are beginning to talk about the need for a focus on tertiary prevention. Given the early onset of most psychiatric disorders, this is clearly a vitally important area for future work.

Within this broad framework there is a wide variety of intervention strategies, some of which may take developmental issues into account. A good example is suicide prevention, which was comprehensively reviewed by Gould and colleagues (M. Gould, Greenberg, Velting, & Shaffer, 2003). Among the primary prevention efforts they discuss are gun control programs at the national and local level and schoolwide suicide awareness curricula. Secondary preven-

tion efforts have included skills training programs for youth, whether identified through screening or self-referred, screening programs to try to identify children with suicidal ideas, training for gatekeepers such as primary care pediatricians, peer counseling programs, crisis centers, and hot lines. Other approaches include training the media on how to report suicide so as to minimize "copy cat" behavior, and postsuicide counseling in schools and among the friends of youth who have killed themselves. Tertiary care programs focus on following up suicide attempters in an effort to reduce repeat episodes. Research on the effectiveness of all these strategies is patchy, and some continue to be used despite doubts about their developmental appropriateness and effectiveness (M. Gould et al., 2003). However, suicide is one of the few areas in child and adolescent mental health in which one can see the skeleton of an integrated prevention strategy beginning to emerge.

It sometimes feels as though progress in implementing prevention programs in the mental health area has been glacially slow, and public policy often impervious to evidence. But prevention scientists are determined people, and they are building a powerful set of weapons in the form of statistical methods, meta-analytic studies, and cost-benefit analyses that will help them to get their message across in the next decade.

Burden of Illness and Costs and Effectiveness of Interventions

As we described earlier, epidemiology (the study of where, when, why, and to whom diseases occur) has a dual role: to increase our understanding of what causes an illness (scientific epidemiology) and to help institute policies to prevent or control it (public health epidemiology). Implementing policies to prevent or control disease costs money. Before allocating resources to any disease, policymakers need to know how big the problem is, what interventions are available, how useful they are, and how much they cost. So epidemiology has historically been concerned with estimating the burden of disease and the cost and effectiveness of interventions (E. J. Costello & Angold, 2000).

Developmental epidemiology has a new role to play in this area, for all the reasons discussed in the section on life course epidemiology. It is becoming increasingly clear that we cannot afford to wait to intervene until, for example, a child develops Conduct Disorder. Treatment at that stage is expensive, labor-intensive (Henggeler, Melton, Brondino, Scherer, & Hanley, 1997), and of modest effectiveness (Lipsey & Wilson, 1998). It is imperative that we apply what is known about early predictors to develop interventions that

can be used earlier in the development of the disorder. This is an enormous research program and is addressed elsewhere in these volumes.

The role of the developmental epidemiologist is often that of record keeper: to measure the burden of disease (World Health Organization, 1996), the need for (E. J. Costello et al., 1993; Rice, Woolston, Stewart, Kerker, & Horwitz, 2002), cost of, and barriers to services (Flisher et al., 1997; Leslie, Rosenheck, & Horwitz, 2001; Owens et al., 2002) at different developmental stages, and the changes in disease incidence as new interventions are introduced (C. H. Brown, Berndt, Brinales, Zong, & Bhagwat, 2000; Ialongo et al., 1993; Kellam, Rebok, Mayer, Ialongo, & Kalodner, 1994).

None of these activities is new to epidemiology in general, but they have been a long time coming to the area of child psychiatric disorders. The next decade will see a significant expansion of cost, cost-benefit, and cost-effectiveness studies, either as new studies or as additions to ongoing ones.

Mental Health Surveillance

Tracking the prevalence (ongoing cases) and incidence (new cases) of diseases over time is a basic task of epidemiology, but one that has hardly begun in the area of child psychopathology. We rely on agencies of the Centers for Disease Control and Prevention (CDC) to tell us how many cases of SARS there were last year in the United States, and whether the incidence of AIDS is increasing or decreasing. But it would be no use to ask CDC the same questions about prepubertal depression or early-onset Schizophrenia; no one there is responsible for these disorders, although their social cost may well be as high (Murray & Lopez, 1996). One exception to this is the area of drug use and abuse, on which annual surveys of the school-age population have been available since 1975 from the University of Michigan's Institute for Social Research. Thirty years of data can be tracked to show the rise and fall in use of different drugs. Another exception is the CDC's Youth Risk Behavior Surveillance System, an anonymous population survey set up in 1990:

to monitor priority health risk behaviors that contribute markedly to the leading causes of death, disability, and social problems among youth and adults in the United States. These behaviors, often established during childhood and early adolescence, include tobacco use, unhealthy dietary behaviors, inadequate physical activity, alcohol and other drug use, sexual behaviors that contribute to unintended pregnancy and sexually transmitted diseases, including HIV infection, [and]

behaviors that contribute to unintentional injuries and violence. (Kann, 2001)

These data can be used to show, for example, a small but steady decline in the proportion of children who had their first alcoholic drink before age 13, from 32.7% in 1991 to 27.8% in 2003. On the other hand, the proportion making a suicidal attempt serious enough to need medical attention has increased from 1.7% in 1991 to 2.9% in 2003.

Because the data come from different (anonymous) samples each year, they cannot be used to track an individual's progression. They do, however, provide hints of what legal or cultural changes might be doing to the development of risk behaviors across adolescence.

Clearly, a major task for developmental epidemiology in the next decade will be to help CDC to shoulder the task of charting national rates of child and adolescent psychiatric disorders over time, as it has done for national rates of other serious conditions. However, with the exception of these brief anonymous surveys and some work on Autism, little has yet been done. One reason for this is that problems of assessment have made it possible to argue that child psychiatric disorders cannot be measured with sufficient reliability and validity to justify such activities. This is no longer the case. Given the limitations of reliance on verbal report of symptoms, measurement of psychiatric symptoms and syndromes is as reliable as in many other areas of medicine, and there are measures available at many different levels of detail, from brief questionnaires to detailed clinical assessments.

Work is currently in progress to integrate brief psychiatric measures into national surveys such as the National Health Interview Survey (NHIS) and the National Health and Nutrition Examination Survey (NHANES-IV). NHANES has recently been using some modules of the DISC and the DISC Predictive Screener, and the NHIS is using a short questionnaire, the Strengths and Difficulties Questionnaire (Goodman, Ford, Simmons, Gatward, & Meltzer, 2000), that is also used in several other countries. This will make international comparisons feasible. More work is needed to evaluate the validity of these measures across the age range and to assess their usefulness as a measure of the burden of child mental illness in the community. It is clear, however, that in the next decade it will be possible to stop treating assessment issues as research problems to be funded by federal research agencies and move them over to being issues to be dealt with by surveillance and monitoring agencies such as CDC. This will have many advantages. First, it will make it possible to treat psychiatric disorders as on a par with other medical condi-

tions. Second, it will produce national data sets, such as those produced by NHIS, that can be used to look at the sorts of questions raised by life course epidemiology: what environmental, political, and social conditions breed psychiatric disorders, and how societies should address these problems. Third, it will relieve the National Institute of Mental Health scientific research budget of the responsibility for basic prevalence studies and free up research dollars for questions on the scientific side of epidemiology, questions about causes and consequences.

This chapter has covered a lot of ground: from the first stirrings of understanding about childhood psychiatric disorders to the possibility of using molecular genetics to identify gene-environment interactions that can generate psychiatric disorder. There are fuzzy boundaries between developmental epidemiology and developmental psychopathology, life course epidemiology, genetic epidemiology, services research, and several other areas. It will be important to keep these boundaries pervious, to share a common language where possible, and to learn and use one another's methods.

REFERENCES 123

At birth and throughout development, males and females differ in obvious and subtle ways. Shaped by evolution and sculpted by culture, these differences have become deeply ingrained. Early in civilization sex roles were clearly differentiated. Males hunted and fended off foes, while females bore and reared the offspring; both were essential to the success of subsequent generations. These roles became increasingly diversified, modified by socialization, and (except for childbearing) shared over the course of time. Our evolutionary heritage, however, is a reminder of the different biologically based functions for which males and females were prepared. This has influenced to a considerable degree their different roles and status in cultures and societies, as well as their different interests, skills, affective styles, and personality traits. The entrenchment of these sex

differences over time has created different patterns of costs and benefits, as well as different strengths and vulnerabilities. These differences are also reflected in (1) the types of disorders and problems males and females develop, (2) the ways their difficulties are manifested and managed, and (3) how external events impinge on and are interpreted by them. Not only may males and females differ on strengths and vulnerabilities, but also the same quality or trait may have both positive and negative adaptational features.

Research on gender and the development of psychopathology is recent in origin and has focused on three primary issues. The first issue has captured the most attention and involves evaluation of sex differences in the prevalence of psychopathology during different periods of development. The second issue is more complex and focuses on similari-

ties and differences in the antecedents, development, correlates, and consequences of psychopathology in males and females from childhood to adolescence and beyond. This type of research emphasizes identification of developmental trajectories toward psychopathology and includes attention to sex differences in contributory factors and in the outcomes that accrue. The third issue involves sex differences in how problems are expressed.

Prevalence rates for almost all psychiatric disorders and psychological problems reflect a sex-based imbalance (American Psychiatric Association, 2000). Males are overrepresented in some disorders, for example, Autism and Attention-Deficit/Hyperactivity (ADHD), Conduct, and Antisocial Personality Disorders. Females are overrepresented in other disorders, for example, anxiety, mood (except for bipolar illness), eating, and Borderline Personality Disorder. Forms of self-injury differ; males are more accident-prone and likely to commit suicide, whereas females more often attempt suicide and engage in body mutilation. Males are more often victims of physical violence, and females are more often victims of relational aggression as well as sexual abuse and physical violence in partner relationships. Even where prevalence rates are the same, there are other differences; for example, males show earlier onset of Schizophrenia than females, and there are differences in symptom expression. Biological and genetic factors can contribute to sex differences in the emergence and developmental course of problems. Boys and girls also experience different socialization, interpersonal relationships, adverse events, and cultural norms that can create different adaptive and maladaptive patterns.

This brief description of differences between the problems of females and males just begins to scratch the surface of a still largely unexplored territory. There are sex differences at all levels of problems (clinical, subclinical, and normative problems), as well as in correlated affective, behavioral, and cognitive styles. Normative variations may inform different manifestations of more serious problems in terms of their antecedents, correlates, and consequences. Conversely, knowledge of contributions to more severe disorders can inform processes associated with more normative patterns of development. A developmental psychopathology perspective is uniquely suited to explore gender-related questions across a continuum of severity of symptoms. Problems more characteristic of males or females are closely tied to different time periods, as the problems of males typically emerge early in development.

Rutter, Caspi, and Moffitt (2003) make the point that sex differences in mental disorders fall into two main groups. There are the early-onset neuropsychiatric disorders, such

as Autism, developmental language disorders, ADHD, Conduct Disorder, and dyslexia, that show a marked male preponderance. Then there are the adolescent-onset emotional disorders, such as depressive/mood disorders, anxiety disorders, and eating disorders, which show a marked female preponderance. Anxiety disorders and antisocial disorders do not fit as neatly into this classification of childhood- versus adolescent-onset. Although anxiety problems peak in adolescence, particularly in girls, anxiety is more common in girls than boys even at an early age. And although the early-onset form of antisocial disorders is associated with neurodevelopmental impairment and more common in males, antisocial disorders also peak again in adolescence.

Because the etiologies of early- versus late-onset disorders may be different, developmental stage becomes a starting point for examining possible causes for different problems in males and females. At the same time, it is necessary to move beyond this dichotomy to consider the (1) early onset of problems in girls, (2) late onset of problems in boys, (3) presence of early signs of problems in both boys and girls that go unnoticed until more pronounced symptoms emerge later in development, and (4) factors that contribute to individual differences *within* groups of boys and girls. We focus in this chapter on childhood and adolescence, but we also consider the implications of developmental processes for some problems first seen in early adulthood but that may have earlier origins. We do not assume that there have to be differential rates of problems for the sex of the child to matter. Rates of a given disorder could be similar for males and females, but they could differ in their manifestations, causes, or patterns of interaction with other etiologic and predictive variables. The study of sex differences in psychopathology at different stages of development requires appreciation of similarities as well as differences between males and females. Increasingly, investigators have come to realize that rather than simply being a nuisance variable, sex differences can provide a means to study causal mechanisms and unravel the complex etiologies that characterize different forms of emotional and behavioral problems (e.g., Crick & Zahn-Waxler, 2003; Rutter et al., 2003).

For a long time, problems commonly were studied in only one sex (more often males). When both males and females were studied in the same research design, results were based on analyses of the total sample. Thus, there was not a comprehensive empirical literature from which to develop hypotheses or generalizations about sex, gender, and the development of psychopathology. This has started to change, as investigators have had to confront and explain those pesky but intriguing differences that often emerge when separate analyses are conducted for males and females. A confluence

of factors makes the time ripe for significant headway in theory and research. Following recognition that physical health problems often differ in the two sexes, public funding of mental health research now mandates inclusion of both females and males in research designs. New and improved technologies and methodologies for studying both biological and psychosocial processes have also contributed to a more substantial database. This makes it possible to begin to characterize the variety of ways in which females and males differ on average. Clinicians and scientists now focus more intensively on problems that have been underinvestigated in one sex because they occurred less frequently, for example, aggression, antisocial behavior, and violence in girls (Bell, Foster, & Mash, 2005; Putallaz & Bierman, 2004) and depression in boys (e.g., Gjerde & Block, 1996; Pollack, 1998).

The terms *sex* and *gender* have been used in various ways and often are used synonymously (Maccoby, 2004). Typically, *sex* refers to the biological differences between males and females. The term *gender* was introduced to distinguish sociocultural forces from biological processes, but this distinction has proved difficult to maintain. Historically, the study of sex differences focused on how and why average differences in personality, cognition, emotions, ability, problems, and/or biological and genetic factors between the sexes might arise. In most cases, sex differences in some quality or behavior occur with overlapping distributions, sometimes with highly sex-differentiated “tails” of the distribution. Most disorders and symptoms have both overlapping distributions and clearly sex-differentiated tails.

In many cases, this focus on differences between two groups of individuals (i.e., males and females) has ignored the large within-sex variance. Some have argued that this can exaggerate, reinforce, and even create sex differences in the minds of others. Although there are problems with accurate estimation of differences in rates, it is now clear that the differences are not simply artifactual but do actually exist (Hartung & Widiger, 1998). But less attention has been paid to the enormous within-sex variability, for example, in antisocial patterns in girls and depression in boys. By focusing on within-subject variability, simultaneously for males and females, we will come closer to understanding etiologic factors that operate both similarly and differently for the two sexes.

The term *gender* is also used to describe power relations in social structures throughout cultures (Stewart & McDermott, 2004). According to this viewpoint, absent other cues and definitions, maleness signals authority, status, competence, social power, and influence, and femaleness signals lack of authority, low status, incompetence, and little power and influence. Gender also signals more positive as-

sociations with femaleness (e.g., compassion, nurturance) and more negative ones with maleness (e.g., psychopathy, violence). Power relations may play some role in different rates and etiologies of symptoms in males and females.

Rutter et al. (2003) recently argued for the appropriateness of using the terms *gender* and *sex* interchangeably in discussions of their role(s) in psychopathology. Maintaining the distinction, they argue, creates an artificial dichotomy suggesting that biological and environmental processes are distinct and fully separable, both conceptually and in terms of measurement and evaluation of causal mechanisms. In this chapter, we use the term *sex* to characterize findings where research subjects have been classified as male or female. Otherwise, we use *sex* and *gender* interchangeably to avoid the different causal implications.

Most of the empirical efforts have focused on biological *or* environmental factors that distinguish between males and females in their relative rates of disturbance, with little emphasis on how these factors interact to influence developmental outcomes. At one end of the continuum, some disorders, such as Autism, result primarily from genetic, neurological, and other more biologically driven factors. At the other end, environmental factors play a major role (e.g., maltreatment). However, even here, biological predispositions cannot be dismissed, just as environmental factors could alter the expression and severity of autistic behaviors. Between these two extremes is a wide range of other emotional and behavioral problems and disorders where both biological factors and environmental processes are likely implicated. To a greater or lesser degree, then, the emergence, progression, and remission of psychiatric and psychological problems will reflect complex interactions of biological and environmental factors, and these factors will not be fully separable. This again highlights the need for a developmental psychopathology perspective and the use of stress-diathesis models to examine the best approximations possible of endogenous and exogenous processes. It will be important to determine the roles of these different sets of factors and the ways they combine and interact for different types of disorders and problems. Some processes may cut across types of disorders; others may be specific to particular disorders.

Mechanisms that could explain sex differences include a number of possibilities: Boys and girls may (1) be exposed to different environmental risk and protective factors, (2) be exposed to different levels of the same environmental risk and protective factors, (3) have different biological processes or mechanisms of gene expression (such that these influences may be differentially amplified or diminished for one sex or the other), (4) require different

thresholds of biological or genetic risk for serious problems to develop, and (5) differentially experience interactions of these environmental and biological/genetic influences. Also, certain biological and environmental processes are expected to operate similarly for males and females.

In short, any number of possibilities may apply, depending on varying constellations of factors. This highlights the need to avoid premature conclusions about similar or different operative processes for the two sexes based on a limited number of studies. Both scientific parsimony and cultural ideologies of equality tend to favor explanations that view the nature and causes of problems in males and females as similar. However, research designs often have not been adequate to address the question of similar versus different causes (e.g., only one sex is studied; samples are not large enough to conduct analyses separately for females and males; constructs are not adequately measured). In our view, this has interfered with identifying potential factors that might lead to differential processes and patterns of psychopathology.

In this chapter, we consider a range of conceptual, methodological, statistical, and substantive issues in the study of sex differences in the development of psychopathology. We review salient issues in the context of specific disorders/problems and also examine crosscutting themes. This includes discussion of comorbidity of problems, which is quite common and differs for males and females. We also consider underlying processes across disorders that may create differential risk; for example, the notion of the extreme male brain has been used to explain the increased likelihood of multiple male-preponderant disorders. To our knowledge, no one has proposed the counterpart of the extreme female brain that may be associated with increased likelihood of multiple female-preponderant disorders; we consider this possibility as well. At the same time, we believe it is important not to reduce the issue of sex differences to one of male versus female disorders, given the enormous overlap for both normative and pathological processes. It is essential to avoid developing sex stereotypes of the problems males and females face. We attempt to provide a balanced perspective that takes these issues into account, considering both similarities between the sexes as well as differences that have begun to emerge.

We begin with a discussion of biological and genetic sex differences that may contribute to different patterns of resilience and vulnerability in females and males. This literature is based primarily on research with animals and adult humans. We then provide a descriptive summary review of the principal domains in which girls and boys differ, normatively, in infancy, childhood, and adolescence, as well as

differ in the environments they experience. Many of the themes that emerge here resurface in subsequent sections on specific disorders and problems as we discuss biological and environmental processes implicated in rates, trajectories, and outcomes for boys and girls. We consider problems in four areas: (1) pervasive developmental (Autism and childhood Schizophrenia), (2) externalizing (ADHD, Oppositional-Defiant Disorder, Conduct Disorder, and substance use), (3) internalizing (depression, anxiety, eating), and (4) personality. We highlight what is known about the prevalence, nature, etiology, and theories of each disorder in males and females. Because there is considerable variation on what is known, the sections vary in length and organization. Last, we discuss problems, progress, and future directions for theory and research on sex differences in psychopathology.

BIOLOGICAL SEX DIFFERENCES

Sexual dimorphisms of behavior are often assumed to be derived from sexual dimorphisms of the brain and body. Evolutionary explanations for sexual dimorphisms also implicate biological underpinnings of behavior to explain sex differences in behavior. Understanding sex differences in biological mechanisms is twofold. A wealth of literature documents robust sex differences in biological systems. Animal studies also demonstrate sex differences in neural circuitry and neurotransmitter systems. These studies highlight the importance of understanding masculinization, the process of becoming more male-like (e.g., development of testes, penis, and scrotum; induction of male traits) and defeminization, the process of removing female-like traits (e.g., regression of female internal ducts; R. J. Nelson, 2000). Parallel studies in humans are now beginning to accumulate evidence for the male and female brain. Apart from obvious physical differences between males and females, however, discovering the implications of biological sexual dimorphisms for normative and risk behavior is an important next step toward understanding sex differences. Here we review biological mechanisms that may contribute to sex differences in psychopathology, including genes, hormones, neurotransmitters, brain development, and pharmacokinetics.

Genetic Contributions

At the most basic level, males and females differ in their genetic makeup. The Institute of Medicine (2001) report appropriately titled the first two chapters “Every Cell Has a Sex” and “Sex Begins in the Womb,” thereby emphasizing

the developmental significance of genetic contributions to sex dimorphisms. In addition to the observation that females have two X chromosomes and males have one X and one Y chromosome, which contains the SRY gene that will later cause the bipotential gonad to differentiate as a testes, females and males differ genetically in other less obvious ways. These include complete and incomplete X inactivation, enzymatic and hormonal interactions, nonrandom allele distributions, and sex selection. Each of these processes may contribute to different pathways of development in males and females beginning when the ovum and sperm fuse.

Within each cell in a female, one X chromosome is inactivated (Latham, 1996). On a cell-by-cell basis, a maternal or paternal X chromosome will be expressed. X inactivation renders females less susceptible to X-linked mutations (e.g., color blindness) and potentially may contribute to their reduced susceptibility to male-dominated psychopathology that tends to begin early in childhood (reviewed later). Further, the process of X inactivation is not complete, so females are exposed to 10% to 15% greater quantity of X-derived proteins (Disteche, 1995). Recent magnetic resonance imaging (MRI) studies show that X inactivation and incomplete inactivation patterns contribute to sex differences in brain areas related to emotion and mood (J. N. Giedd, personal communication, August 19, 2004 by telephone).

Within each cell in a male, one Y chromosome is expressed. The Y chromosome codes for few genes (only eight in mice), but among these few is the SRY gene. The SRY gene has received much attention because it codes for testes differentiation and the eventual cascade resulting in testosterone secretion from the developing male gonads. Appreciating the fact that the Y chromosome codes for more than testes differentiation will lead to a greater understanding of Y chromosome functions not directly linked to SRY and testosterone (Arnold, Rissman, & De Vries, 2003). A provocative line of research aimed at isolating the direct effects of the SRY gene versus other Y chromosome effects in the brain and on behavior revealed that sex accounted for more of the variation in the brain and behavior of mice than the complement of the SRY gene (in genetic XX or XY mice). This suggests that masculinization and defeminization in the brain are due to hormonally mediated genetic effects (i.e., SRY-specific effects), as well as other Y-linked sources of sexual differentiation (De Vries et al., 2002). Further, genetic differences between males and females lead to enzymatic and hormonal sex differences (reviewed extensively in Migeon & Wisniewski, 1998). Some genetic differences are derived from the X

and Y chromosomes, but many genes, enzymes, and hormones become dimorphic by interacting with X- or Y-linked biomarkers. For example, at least seven enzymatic steps are necessary for converting cholesterol to testosterone and dihydrotestosterone (DHT); these enzymes are not located on the Y chromosome (MacLaughlin & Donahoe, 2004). Nevertheless, the end point of this process becomes fundamentally different in the male and female (Migeon & Wisniewski, 1998, 2003). Testosterone, in turn, regulates gene expression differently in the male and female and is more heritable in the male than in the female (Hong et al., 2001). Genetic differences between males and females may also exist if allele determinism is nonrandom or if genetic expression of an allele interacts with promoters on the X chromosome. This would result in males and females having different patterns of gene expression derived distantly from their XX or XY complement.

Although chromosomal endowment is arguably the furthest domain from which social processes influence sexually dimorphic mechanisms, nevertheless social factors can influence gene expression, leading to gene-environment correlations and interactions, and Grant (1996, 1998) has proposed a theoretical model in which social processes influence sexual determination (i.e., likelihood of conceiving males or females). Thus, dominant women with high testosterone are more likely to conceive sons, particularly when times are tough, and thereby parent the gender that they are most suited to raise. If the physiological mechanism for Grant's hypothesis is supported, then this idea is a good example of the negligible value of rigidly distinguishing between biological and social forces that influence sex and gender (Rutter et al., 2003). It is also an intriguing example of a biosocial interaction in which genetic and biological forces may be exacerbated by social phenomena. In sum, gender differences may be due to chromosomal differences arising from (1) chromosomal dissimilarities related to inactivation, (2) biological processes related to other chromosomes or hormonal factors that interact with the X and Y chromosomes, or (3) enzymatic differences resulting from other chromosomes.

Neuroendocrine Contributions

Hormones are powerful regulating factors that influence gene expression. W. C. Young, Goy, and Phoenix (1964) first presented the *organizational-activational hypothesis*, based largely on rodent and primate models, which postulates that following some genetic signal, androgenic hormones directly cause the masculinization and defeminization of brain mechanisms of behavior during a critical

period early in development. Masculinization occurs on a continuum as a function of the amount of hormone present in utero. These masculinizing hormones exert an effect on behavior independent of circulating hormones. After a period of relative quiescence (e.g., the juvenile period), these circuits that were organized by androgens are later activated (Hutchison, 1997). Many researchers still consider (implicitly or explicitly) gonadal steroids to instantiate sexual differentiation of the human body, brain, and behavior (Arnold et al., 2003).

Based on the timing and duration of effects, neuroendocrine influences on the brain and behavior are divided into organizational effects, processes initiated and terminated in utero, and activational effects, processes initiated after the termination of the juvenile period. Activational effects must be further differentiated into developmental opportunities at puberty, concurrent effects in late adolescence or adulthood, cyclical activation, and disorganizational effects (McEwen, 1992). The study of sex differences in hormones must necessarily consider the developmental stage at which effects begin, when they are observed and measured, how long effects last, and other biosocial forces expected to influence pathways of development (Udry, 2000). Before reviewing sex differences in hormone effects, however, a note of caution is warranted. Many studies that assess the organizational-activational hypothesis are based on animal models of behavior. Animal models are informative but are more simple than the human condition. Research in humans is often limited to correlational studies conducted at opportunistic developmental stages (Udry, Morris, & Kovenock, 1995) or on experiments of nature, that is, intersex individuals (see reviews by Migeon & Wisniewski, 1998, 2003). Experiments of nature provide powerful evidence for both the diversity of neuroendocrine effects on sex differences and the intense environmental factors that play critical roles. Overemphasizing either biological or environmental contributions to the organization of sex differences has had drastically bleak effects on the quality of life of intersex individuals (see Bradley, Oliver, Chernick, & Zucker, 1998, and M. Diamond & Sigmundson, 1997, for an ongoing debate). Recent historical events should remind us all that disentangling neuroendocrine contributions to sex differences must necessarily acknowledge the complexity of these effects (Colapinto, 2000; <http://slate.msn.com/id/2101678>).

Studies on intersex individuals have provided support for the organizational-activational hypothesis but have also added much additional complexity to human sexual differentiation (Migeon & Wisniewski, 1998, 2003). A full review

of the neuroendocrinology of experiments of nature is beyond the scope of the current review. Nevertheless, two brief examples are described to illustrate the limitations of the view that gonadal steroids are simple mediators of sexual dimorphisms. Genetic mutations in the gene coding for the testosterone receptor cause genetic XY individuals to be unable to respond to testosterone (when the mutation is complete rather than mosaic), and these individuals, by and large, have female sexual identity. On the other hand, the adrenal gland of congenital adrenal hyperplasia individuals makes androgens instead of corticoids. Consequently, these individuals are prenatally exposed to heightened androgen levels and experience some physical, neural, and behavioral masculinization, although, by and large, they retain female sexual identity. A complex picture emerges, then, in which the addition of testosterone does not lead to masculine gender identity, but the subtraction of testosterone leads to feminine gender identity. This simplistic supposition is meant to demonstrate that the central tenets of the organizational-activational hypothesis may remain unchallenged, but human development imparts complexities for biological processes that contribute to the development of masculine and feminine sexual identity (see M. Diamond & Yates, 2004, and MacLaughlin & Donahoe, 2004, for reviews).

Organizational effects of hormones begin after the testes differentiate in utero, and the testes begin to secrete testosterone and Müllerian inhibiting hormone. Testosterone directly causes the masculine internal structures to differentiate and, through its conversion to DHT, indirectly causes the masculine external genitals to differentiate. Müllerian inhibiting hormone causes the internal female structures to regress. Testosterone also indirectly causes brain structures to be masculinized through its conversion to estrogen. Testosterone, more easily than estrogen, readily crosses the blood-brain barrier; testosterone is then converted to estrogen in the brain by the enzyme aromatase. Most evidence indicates that estrogen is responsible for defeminizing and testosterone is responsible for masculinizing brain structures (Hutchison, 1997). In humans, the default is female, which means that female sex will develop prenatally in the absence of a signal from the testes. Without the SRY gene, the bipotential gonad will develop into an ovary; without DHT, the external genitals will proceed to develop into labia and clitoris; and the internal female structures will proceed to develop in the absence of Müllerian inhibiting hormone (see Collaer & Hines, 1995, and Hines & Collaer, 1993, for reviews).

Beginning in early infancy and nearly complete by 2 years of age, there is a period of relative quiescent hormonal activity. *Activational effects* begin when hormone

levels rise during adrenarche and gonadarche. Circuitry originally organized by gonadal steroids become operational again at this hormonal signal, although the precise trigger of this developmental stage remains unknown (Grumbach, 2002). This process begins earlier in girls than boys. Although sex differences at the hypothalamic level appear negligible, the end point of the gonadotropin-releasing hormone (GnRH) pulse generator is different in males and females: (1) Hormone release is cyclical in females but not in males; (2) target organs differ in girls and boys (i.e., ovaries and testes); (3) the source organ of androgens in males is the testes, and in females it is predominantly the adrenal gland; (4) hormone levels of androgens and estrogens differ in boys and girls (Grumbach, 2002); and (5) the measurement of steroids is different in boys and girls (Granger, Shirtcliff, Booth, Kivlighan, & Schwartz, 2004).

Although animal models reveal robust sex differences in the activational role of gonadal steroids, effects in humans appear more subtle (see McEwen, 2001, 2002; McEwen & Alves, 1999). In one of the strongest tests of activational effects of gonadal steroids, Finkelstein and colleagues (Finkelstein et al., 1997, 1998; Liben et al., 2002; Schwab et al., 2001; Susman et al., 1998) conducted a randomized, double-blind, crossover placebo-controlled trial on adolescents with delayed puberty. Males were injected with testosterone and females were injected with estrogen in increasing dosages meant to mimic natural puberty. Effects of testosterone and estrogen on behavior problems, aggression, mood, sexual behavior, spatial ability, and cognition were surprisingly sparse. Despite the fact that gonadal steroids conspicuously rise at the time that sex differences emerge in a broad range of behaviors, direct causal links have yet to be found in humans, but are likely to be permissively related to sex differences (Grumbach, 2002). Studies on concurrent activational effects of steroid hormones reveal small yet robust sex differences in hormone-behavior relationships (Steiner, Dunn, & Born, 2003). Emotion regulation, mood, and psychopathology appear to have a small yet robust relationship with testosterone and estrogen, respectively (Alexander & Peterson, 2004; Booth, Johnson, & Granger, 1999; McEwen & Alves, 1999). These associations must be understood in the context of critical windows of opportunity, changing biological paradigms, and complex interactions with other biological systems (see Rubinow & Schmidt, 1996, for a review). Indeed, interactions with other systems have provided some of the most interesting neuroendocrine data to date.

In addition to sex differences in gonadal steroids, other hormones also show consistent sex differences, and the moderating role of gonadal steroids can change the func-

tional role of other hormones differently in boys and girls. For example, the hypothalamic-pituitary-adrenal (HPA) axis interacts extensively with gonadal steroids (Viau, 2002), with testosterone suppressing and estrogen enhancing activity of the HPA axis (Rhodes & Rubin, 1999). This may render females more responsive to the long-term consequences of stress. Estrogen and progesterone exert a protective effect for females' stress response, but at the same time, these hormones also dampen negative feedback mechanisms of cortisol on earlier stages of the HPA axis. Consequently, the ability of females to recover from stress may be delayed compared to their male counterparts (E. A. Young, 1998). Similarly, Taylor and colleagues (2000) have proposed that the female response to stress is fundamentally different from that of males in that oxytocin and endogenous opioids are central to the tend-and-befriend response to stress in females, whereas vasopressin is implicated more in males (Insel & Fernald, 2004; Rhodes & Rubin, 1999). Further, estrogen heightens the tend-and-befriend stress response, and testosterone dampens it. Consequently, this pathway is more easily accessed in females than males (Taylor, Lewis, et al., 2002).

Finally, social moderators of the stress response such as social support behave differently in females than males (Kirschbaum, Klauer, Filipp, & Hellhammer, 1995; Taylor, Dickerson, & Klein, 2002). The HPA and HPG (hypothalamic-pituitary-gonadal) axes, and the social moderation of these interactions, may also behave differently in boys and girls at puberty (Hayward & Sanborn, 2002) and in utero (Reznikov, Nosenko, & Tarasenko, 1999). Maternal stress prevents the development of sexual dimorphism in the brain; administration of hydrocortisone exerted parallel effects, suggesting that early in development the gonadal and adrenal steroids are mutually dependent (Reznikov et al., 1999). The role of gonadal steroids as causes and consequences of sex dimorphisms is complex; it changes with development, is modified by other systems, and appears cyclical (McEwen, 2001; McEwen & Alves, 1999). It is the rule, rather than the exception, that gonadal steroid changes result from earlier biological interactions. These steroids in turn change higher processes through positive or negative feedback mechanisms (Hutchison, 1997).

There are challenges to understanding biological contributions to sex differences in psychopathology due to the limited critical window for the timing of sexual differentiation. Without that information, understanding the mechanisms behind further sexual differentiation later in development is confounded by earlier processes and concurrent change (Institute of Medicine, 2001; Rutter et al.,

2003). The *organizational-activational hypothesis*, at face value, posits that gonadal steroids are central to sexual dimorphisms of the brain and behavior. Consequently, hormonal manipulations should uncover mechanisms behind sexual dimorphisms. When gonadal steroids are not implicated, as is often the case in practical settings, it is unclear whether this is due to inaccurate hormonal measurement or timing, to complex biological interactions, or because other factors account for the dimorphism. It is disconcerting that when gonadal steroids are not key statistical mediators, researchers interpret this to be *de facto* proof of social and cultural forces. Rather than elucidating dimorphic mechanisms, this view has contributed to a poor understanding of complex biological and biosocial mechanisms of sexual dimorphism and, in turn, their respective malleability. A developmental science perspective is a useful framework for refining our current level of understanding by emphasizing multiple levels of analysis, biosocial and bio-bio interactions, the importance of time and timing, and the critical appreciation of context (Cairns, Elder, & Costello, 1996).

Neurotransmitter Levels and Activity

There are sex differences in neurotransmitter levels and function. Patterns of sex differences in neurotransmitters change across development, providing further support for the idea that sex differences are derived more from differences in the pattern of biological expression, timing, and duration of biological changes than from differences in levels and expression of a hormone or neurotransmitter. Diverse consequences of castration, for instance, point to the complex regulatory role of gonadal steroids in the development of brain circuits and neurotransmitter function (Rubinow & Schmidt, 1996; Sumner & Fink, 1998). This section emphasizes developmental effects in its review of sex differences in neurotransmitters, including gamma-aminobutyric acid (GABA), glutamate, acetylcholine, dopamine, and serotonin (5HT).

GABA is an inhibitory neurotransmitter with implications for psychopathology treatment and intervention (see reviews by Krystal et al., 2002; Petty, 1995). GABA has receptors located nearly everywhere in the brain but notably in sexually dimorphic brain areas (McCarthy, Auger, & Perrot-Sinal, 2002). GABA has extensive connections in the hippocampus, thalamus, and hypothalamus and thereby is regulated by and helps to regulate the HPG axis (McCarthy et al., 2002). Early in fetal development, GABA is actually excitatory (Owens & Kriegstein, 2002), and it is during this window of excitation that GABA is centrally involved in sexual dimorphisms of the developing brain. According to

McCarthy and colleagues (2002; McCarthy, Davis, & Mong, 1997), gonadal steroids increase excitatory functions of GABA. Increased neuronal excitability during this sensitive period, in turn, cause permanent cytoarchitectural differences in the male brain, predominantly at the level of synaptogenesis and apoptosis more so than cell migration. These positive steroid-GABA feedback loops are notable in the hypothalamus, bed nucleus of the stria terminalis, and medial amygdala. Because male brains have heightened exposure to testosterone and, through aromatization, to estrogen, they are exposed to higher levels of GABAergic neuronal excitation, which permanently masculinize the brain. Thus, GABA, in conjunction with gonadal steroids, is directly implicated in sexual dimorphisms of the developing brain.

Around the same developmental window (Sims & Robinson, 1999), sex steroids up-regulate glutamate. Glutamate is an excitatory neurotransmitter, which has been implicated in forms of psychopathology such as Schizophrenia, Posttraumatic Stress Disorder (PTSD), and Anxiety Disorders (Bergink, van Megen, & Westenberg, 2004; Chambers et al., 1999; Goff & Coyle, 2001; Schiffer, 2002) and is a key component of Sapolsky's (1990) model of neurotoxicity and mechanisms of neuron death. Sex steroids modulate neurotransmission of glutamate, which leads to increased excitation, particularly in males and the limbic system. Glutamate is central to the regulation of sex steroids by GnRH in the hypothalamus such that testosterone and estrogen regulate release of glutamate from the hypothalamus, and glutamate causes the release of GnRH and the activation of the HPG axis. Glutamate's role is distinct from GABA by remaining excitatory in both males and females (Grumbach, 2002), but the male brain is exposed to more neuronal excitation as a result of both GABA and glutamate (McCarthy et al., 1997).

Acetylcholine is an extremely diverse neurotransmitter integrally involved in cognition, notably attentional processes, learning, and memory (Berger-Sweeney, 2003). Acetylcholine has a multifarious sex difference in that the cholinergic system is more sensitive in females, but the system is larger in males. Differences in the timing of the development of the cholinergic system may help explain sexual dimorphisms in acetylcholine-mediated processes (Berger-Sweeney, 2003). Rhodes and Rubin (1999) postulate that, compared to males, females show more functional sex differences in acetylcholine. Females have higher levels of acetylcholine and more cholinergic uptake and activity, and their cholinergic system is more sensitive to blockade and stimulation. Compared to females, males show more dimorphism, or structural sex advantages: Brain areas with cholinergic projections are bigger in males than females,

and they have more cholinergic receptors. Thus, males and females may achieve equivalent cholinergic activity through diverse means (i.e., equifinality). Sex differences in acetylcholine may account for sex differences in psychopathology if females and males prove to have different propensities for disequilibrium in the cholinergic system (Rhodes & Rubin, 1999). One way males and females may achieve functional sex differences in acetylcholine is through interactions with estrogen (McEwen, 2001; McEwen & Alves, 1999) or other gonadal steroids (Rubinow & Schmidt, 1996).

Dopamine has obvious links to reward, sexual behavior, and psychopathology (Diehl & Gershon, 1992; Hietala & Syvalahti, 1996; Schultz, 2001). In addition, dopamine has extensive connections with sex hormones, including testosterone, estrogen, and progesterone (Di Paolo, 1994), and dopamine activity is altered by castration (Quinones-Jenab et al., 2001). Dopamine is centrally related to appetitive social interactions in the model of the social brain proposed by Insel and Fernald (2004). Briefly, Insel (2003) suggests that the dopaminergic neural circuitry for reward is also responsible for establishing active maternal motivation. Through interactions with oxytocin during a critical window when maternal behavior is established and in sexually dimorphic brain areas rich with estrogen receptors, dopamine helps females become “addicted to love” (Insel, 2003). Formation of partner preference in males, through activation of vasopressin rather than oxytocin, is also postulated to be derived from social information connecting to dopaminergic reward circuitry (Insel & Fernald, 2004). Human functional magnetic resonance imaging (fMRI) studies also show reward circuitry being activated in response to maternal and romantic love (Bartels & Zeki, 2000, 2004). Dopamine is thus postulated to have functional sex differences that relate closely to the appetitive cues of sex, maternal, paternal, and social cues.

Insel (Insel & Winslow, 1998) also identifies 5HT as a neural substrate of social and affiliative behavior. Sex differences in this model are instantiated as estrogen, oxytocin, and dopamine activity in the female (reviewed earlier) but testosterone, vasopressin, and 5HT activity in the male. Although Insel’s model does not further explicitly address sex differences, Taylor et al. (2000) postulate that females are more invested in social recognition and use this regulation system when experiencing stress more than males, although the underlying circuitry operates in both males and females (Geary & Flinn, 2002). Sex differences in 5HT are complicated by the diverse functions of 5HT receptor type, number, and distribution in addition to dynamic interactions with sex hormones. Much attention

has focused on the 2A receptor subtype because it is distributed in brain areas related to emotion and mood (Bagdy, 1998). Females are less responsive to 5HT than are males; 5HT receptors are down-regulated in females; there is more receptor binding in males. On the other hand, females have higher baseline 5HT levels, more serotonergic fibers in sexually dimorphic areas of the brain, a more potent response to antidepressants than males, and are more sensitive to the anxiolytic effects of 5HT agonists (see Zhang, Ma, Barker, & Rubinow, 1999). In humans, positron emission tomography studies show that there is more 5HT 2A binding in men than women in frontal and cingulate cortices, brain areas related to mood disturbance, and postmortem studies of depressed men and women reveal higher levels of 5HIAA in females (Biver et al., 1996). Serotonin interacts extensively with both estrogen and testosterone. Estrogen exerts a regulatory role over 5HT 2A receptor activity, whereas testosterone is coupled more closely with 5HT 1A receptor activity. Castration increases 5HT 1A receptor activity in mood-related brain areas, and administration of testosterone reverses these changes (Zhang et al., 1999). Conversely, estrogen primarily regulates 5HT 2A receptor activities in brain areas related to mood and cognition (Fink & Sumner, 1996). Testosterone administration likewise changes 5HT 2A receptor function, but this appears to be mediated by its conversion to estrogen in aromatase-rich brain areas (Fink, Sumner, McQueen, Wilson, & Rosie, 1998; Sumner & Fink, 1998). An additional sex difference in 5HT exists in that sex hormones regulate 5HT differently in males and females (McEwen, 2001; McEwen & Alves, 1999), suggesting that serotonergic activity in males and females differs at multiple levels of analysis.

In sum, the literature on sex differences in neurotransmitter levels and function emphasizes diverse functions in various neurotransmitters. Sex differences in one component are often balanced by opposing sex differences in another. This literature thereby emphasizes equifinality, the process of achieving the same end through different means (discussed more later). This review has de-emphasized the specific neural circuitry involved with each neurotransmitter, though clearly, neurotransmitters function differently across structures.

Brain Structure and Function

A wealth of animal research has been devoted to understanding the nature of sex differences in neural structure and function. This literature highlights interactions of go-

nadal steroids with neural circuitry related to sexual function, including Phoenix and Goy's original work (1967), and behaviors with clear sex differences, such as spatial abilities, aggression, and male bird song (Collaer & Hines, 1995; Ruble & Martin, 1998). Often, the organizing effects of genetic and environmental forces are also acknowledged. More attention has been paid recently to human sex differences in neural structures with the advent of structural and functional brain imaging, notably sex differences in developmental trajectories (Giedd, 2001).

Sex differences in human brain circuits are conspicuously scarce. In adults, males have greater cerebrum, cerebral white matter, and ventricular matter, whereas females have greater total cortex volume (Goldstein et al., 2001). The developing male brain is about 10% larger than the female brain. After correcting for brain volume differences, females have a relatively larger caudate, and males have a larger globus pallidus (Giedd, 1997; Giedd, Castellanos, Rajapakse, Vaituzis, & Rapoport, 1997). When overall brain size is controlled, women are sometimes found to have a relatively larger corpus callosum than men (for reviews and different interpretations, see Bishop & Wallsten, 1997; Holloway, Anderson, Defendini, & Harper, 1993). Although the functional significance of this potential difference is unknown, it has been suggested that the relatively larger corpus callosum of women allows the language centers of the left and right hemispheres to communicate with each other. Consistent sex differences in the corpus callosum in children and adolescents have not been noted (Giedd et al., 1996, 1999).

Nonetheless, sex differences in developmental trajectories are intriguing. Interpreting sex differences in the size of brain structures is complicated by the fact that both larger and smaller structures may indicate enhanced function. Larger structures may confer greater protection from neuronal loss or environmental insult; smaller structures may reflect enhanced neuronal pruning with more mature, differentiated brain areas. Giedd and colleagues (Giedd, 1997; Giedd et al., 1997) have shown that the lateral ventricles increased in size in males notably after age 11, but showed more gradual increased size in females. Amygdala volume increased more for males than females, but hippocampal volume increased more in females than males. Many of the dimorphic brain areas are related to mood, emotion, and emotion regulation. For instance, the curve of development of the frontal cortex, caudate, and temporal lobes in girls is considerably faster than in boys, by as much as 20 months. Sex differences in the development of some brain areas, such as the prefrontal cortex, are largely

mediated by age-related changes rather than pubertal transition. Problems in emotion regulation may arise when physical development is not synchronized with brain development or when development in one system is not synchronized with another. For example, frontal lobe development is independent of Tanner stage, but current models show that the development of the limbic system follows the pubertal developmental trajectory. Dahl's (2004) model posits that problems in emotion regulation arise when development of the limbic system, related to the pubertal transition, advances emotion and mood difficulties before the inhibitory and regulatory role of the prefrontal cortex is fully matured. Similarly, Ge and colleagues (Ge, Conger, & Elder, 1996, 2001) suggest that early-maturing girls are at risk for problems because their social and cognitive development is not as advanced as their physical form.

Functional MRI has made it possible to more directly assess sex differences in the neural processing of emotion. For example, McClure and colleagues (2004) found that adult men and women subjectively viewed angry faces similarly, yet women showed greater orbitofrontal and amygdala activation when processing these unambiguously threatening faces. Although this pattern of sex differences was not yet consolidated by adolescence in this study (McClure et al., 2004), another fMRI study found that, compared to adolescent males, adolescent females exhibit greater prefrontal and amygdala activation while viewing fearful faces (Killgore & Yurgelun-Todd, 2001). These studies demonstrate the potential for fMRI to shed light on sexual dimorphisms in affective circuitry and neural processing.

Biological sex differences in brain areas may be derived from genetic, hormonal, or environmental forces. The study of sex differences derived from environmental forces, such as environmental toxins or interactions with stress or challenge, is still in its infancy. Evidence for genetic forces comes from a recent study by Giedd and colleagues (2005) on males with Klinefelter's syndrome, a 46-XXY chromosomal complement. The presence of the Y chromosome makes 46-XXY individuals unequivocally male, but they differ in various behavioral and physical ways from normal males because of enhanced exposure to X proteins that fail to inactivate. The total cerebral volume, frontal and temporal gray matter, caudate nucleus, parietal white matter, and cerebellum were found to be smaller in 46-XXY male brains compared to their XY counterparts. Preliminary evidence also shows that monozygotic (MZ) twin male brains are more similar than MZ twin female brains, and this may be in part because, compared to twin

males, identical twin females are less similar to each other because X inactivation is not complete. Thus, the complement of XY and XX chromosomes can directly affect brain structure and, perhaps, function.

Finally, sex differences in brain areas may also be derived from hormonal influences in utero, at puberty, or concurrently (reviewed earlier). Sex differences in adults were evident specifically in brain areas dense in sex steroid receptors, suggesting a possible organizational role for sex steroids (Goldstein et al., 2001). Much of animal research on sex differences has pursued neuroendocrine mediation of brain volume because brain areas that show sex dimorphisms often have robust patterns of hormone receptors and are often changed by castration and/or hormone replacement. For instance, castration reduces neurotransmitter and brain structure in the cortex, hippocampus, amygdala, hypothalamus, and brain stem. McEwen (1992, 2002) has presented thorough reviews of the relative diversity of functions that hormones have in specific brain areas. This work also emphasizes the complexity of neuroendocrine interactions with neurotransmitters across different brain structures.

In sum, provocative research has begun to highlight small, robust sex dimorphisms in developing brain circuitry. These sex differences are hypothesized to be derived from genetic, hormonal, and environmental forces, though research that distinguishes among these possibilities is scarce. Studies that assess functional sex differences in brain circuitry are of utmost importance for biobehavioral research on psychopathology.

Pharmacokinetics and Pharmacodynamics

The Institute of Medicine (2001) has emphasized how little is currently known about sex differences in pharmacokinetics and, especially, pharmacodynamics. Several different, sometimes conflicting, forces influence how quickly and efficiently males and females metabolize and respond to drugs. For example, an intriguing pattern of gender differences in antidepressant prescription, use, efficacy, and pattern of side effects highlights that the causes and consequences of sex differences in pharmacokinetics and pharmacodynamics will have broad implications for how effectively males and females respond to drugs (see Yonkers, Kando, Cole, & Blumenthal, 1992, for a review). Females are more likely to have atypical depression and consequently are likely to be prescribed tricyclic antidepressants, whereas males are more likely to be prescribed selective serotonin reuptake inhibitors. The response to antidepressants in females will be influenced by their hor-

monal milieu, and thus will change from day to day (Meibohm, Beierle, & Derendorf, 2002). This is because estrogen is itself an antidepressant. Selective serotonin reuptake inhibitors are more effective on days when estrogen levels are high, and women using contraception tend to maintain higher blood antidepressant levels (Yonkers et al., 1992). Slower clearance of antidepressants in females will lead to longer duration of drug effects, but this may practically result in more drug side effects in women than men. Thus, changing and dynamic forces influence sex differences in pharmacokinetics and -dynamics. This section reviews sex differences in bioavailability, distribution, metabolism, and excretion, which can influence how males and females respond to drugs.

Bioavailability refers to the rate and extent of absorption of a drug. Sex differences in many aspects of bioavailability appear negligible, but gastric emptying time is slower in females due primarily to sex hormone interactions (Gandhi, Aweeka, Greenblatt, & Blaschke, 2004). This suggests that females maintain higher bioavailability during some phases of the menstrual cycle (Anthony & Berg, 2002a, 2002b). Sex differences in distribution are often mediated by sex differences in body composition. Females have lower body weight, more fat distribution, smaller organ size and blood flow, and fewer binding proteins depending on the hormonal milieu (Gandhi et al., 2004; Meibohm et al., 2002). Thus, females will, on average, have greater drug distribution. Drug metabolism is primarily influenced by enzymatic sex differences, which will favor males or females depending on the enzymatic interaction. These differences are often subtle and drug-specific and may also vary across the menstrual cycle and with contraception use (Gandhi et al., 2004). Sex differences in excretion favor males in that renal clearance is faster in individuals with higher weight and thus will be, on average, faster in males. However, even after correcting for body weight, males have faster filtration than females (Gandhi et al., 2004; Meibohm et al., 2002). Sex differences in pharmacodynamics are promising avenues for future research (Institute of Medicine, 2001). One consistent sex difference in pharmacodynamics is that females are more susceptible to drug side effects, even when males and females achieve similar levels of the drug in the blood (Gandhi et al., 2004; Meibohm et al., 2002). In sum, through opposing sex differences in pharmacokinetics, males and females may achieve similar drug effects. Some differences are derived from differences in body weight. Others are derived from different susceptibilities of males and females to side effects and pharmacodynamic interactions.

A consistent theme in this review is that sex differences in a specific biological system, area, or mechanism are often countered by an opposing difference in another system, area, or mechanism. Actions of testosterone frequently mirror estrogen. Maternal behavior under the control of oxytocin parallels vasopressin and pair bonding in males. The male advantage of the globus pallidus opposes the female advantage of the caudate, making the basal ganglia roughly similar in size in males and females. Enzymes involved in drug metabolism may favor males or females. Thus, through different biological means, both sexes may achieve similar functional abilities. This observation should not minimize the importance of biological sex differences, but rather highlights the importance of understanding biological subtleties. Because males and females function differently, they have relative strengths and vulnerabilities that may be affected differently when these biological systems are stressed. Geary and Flinn (2002) emphasize this by pointing out that both the tend-and-befriend and fight-or-flight response to stress operate in males and females, but to different degrees. Thus, a similar environmental challenge may exert very different biological force on men and women when each gender activates its primary default system. Because the underlying circuitry is more or less labile in men and women, understanding the biological contributions of sex will not be realized until sex differences in the social environment are also carefully scrutinized. The process of equifinality gives way to multifinality when social and environmental forces take effect (Cicchetti & Walker, 2001).

TYPICAL SEX DIFFERENCES IN CHILDHOOD AND ADOLESCENCE

The development of male and female children shares many common features. From the standpoint of physical development, embryos begin as relatively undifferentiated cellular structures that multiply and differentiate to form the brain, organs, and limbs. At birth, infants already possess largely rudimentary abilities in physical, cognitive, perceptual, social, and emotional functioning that develop throughout childhood and adolescence. Children develop language, motor coordination and physical capacities, thought, emotional expression and control, and interpersonal skills that become expressed in social interactions with familiar and unfamiliar others. Both boys and girls negotiate the developmental tasks of self-regulation (of motor behavior, cognitive activity, emotion), communication (through language and action), and social interaction (e.g., with caregivers, peers; Bell et al., 2005).

As children grow older, they play increasingly active roles in engagements with their environments. One major developmental task of childhood is to become an independent adult, establishing the physical, cognitive, social, and emotional attributes needed to begin to function autonomously in the world at large. Another major developmental task is to become an interdependent adult, establishing corresponding attributes needed to function in relationships with others. Many aspects of these developmental tasks are similar for girls and boys; from an evolutionary perspective, they have also developed different qualities or abilities associated with their later roles in producing and rearing the next generation of children.

Given differences in the biological capabilities and normative roles of adult men and women, the development of boys and girls would be expected to diverge in specific abilities that provide the foundations for these functions (Bell et al., 2005). Children's engagement in gender stereotypical activities consonant with these sex roles are seen in a wide variety of settings, in terms of their free play, chores, interests, activities, and preferences (Ruble & Martin, 1998). These sex-typed differences begin in the first years of life and continue throughout childhood and adolescence. They are undoubtedly linked in complex ways to sex differences in biology, cognition, social and emotional styles, temperament, and socialization experiences.

Biological and Physical Development

Biologically, boys begin with a developmental disadvantage compared to girls. In utero and throughout infancy, boys have lower survival rates, poorer immune function, and slower biological development than girls, with evidence suggesting that prenatal exposure to testosterone accounts for this relative disadvantage (Geary, 1998, 2002; Keenan & Shaw, 1997). High levels of circulating hormones in males also may be associated with slow maturation of parts of the temporal cortex relative to females (McClure, 2000). The faster development of girls has been implicated as a protective factor against mild genetic anomalies and learning disabilities. Boys show more early-onset disorders associated with neurodevelopmental impairment. From a biological standpoint, young girls appear better prepared for the developmental tasks of the early years of life. By school age, boys are about 1 year behind girls in physical maturity (Eme, 1992). There also are possible neurological differences that include, for example, hemispheric lateralization, where there is a right hemisphere advantage for females for processing emotional cues such as facial expressions (McClure, 2000). Beginning in infancy, there is

also evidence of a developmental advantage for the left hemisphere for females for processing verbal stimuli (see Heller, 1993). Although girls may be favored in terms of some biological processes, others may create risk, perhaps for different types of problems.

Biological and hormonal factors have been implicated in boys' and girls' early expression of sex-typed behaviors. For example, hormonal factors have been proposed to account for boys' lower levels of interest in infants and orientation toward people compared with girls (Maccoby, 1998), differences that are already present in the first months of life (Geary, 2002). Toy and play preferences vary as a function of prenatal exposure to hormones, with androgen exposure in girls related to a preference for boy playmates, rough-and-tumble play, and sex-typed boy toys (Ruble & Martin, 1998). By puberty, the advantages of rapid development of females relative to males disappear and may even be detrimental (Hayward, 2003). During puberty, there are dramatic increases in testosterone for boys and estradiol for girls. Hormonal changes associated with puberty (especially early puberty), in females in particular, have been associated with more problems, such as depression. Differences between boys' and girls' physical abilities also increase during puberty (Geary, 2002). Thus, biological development in infancy and childhood favors girls over boys, but this advantage diminishes and sometimes reverses in adolescence and adulthood.

Cognition and Language

When sex differences in language are present, they favor girls (Keenan & Shaw, 1997; Maccoby, 1998; Ruble & Martin, 1998). Boys have more reading problems and other learning disabilities. Young girls have larger vocabularies than boys and show relative advances in using language to label and describe objects, events, and personal experience and preferences. Girls initiate verbal interchanges more often than boys and are more responsive to the verbal communications of others. Although there is little evidence of sex differences in overall cognitive functioning or IQ, girls and boys differ in the ways they attend to and process information (Geary, 1998, 2002). For example, boys and girls remember similar amounts, but different types, of spatial information when engaged in exploratory play; boys remember routes, whereas girls remember landmarks. Even in infancy, boys are more likely to attend to physical aspects of their environments (e.g., lights, sounds), whereas girls tend to attend to the consequences of environmental objects or events (e.g., attending to others' responses). Throughout the school-age years, girls are likely

to show greater academic achievement. But by adolescence, they begin to decline in certain domains relative to boys, particularly in areas having to do with math and science (Ruble & Martin, 1998). Boys excel in spatial skills, particularly mental rotation, more often than girls. The extent to which these differences reflect inherent qualities or socialization is not clear (Jacobs & Eccles, 1992; Jussim & Eccles, 1992).

Emotions and Temperament

A number of sex differences in temperament have been seen in neonates (see review by Weinberg, Tronick, Cohn, & Olson, 1999). Male newborns are less responsive to social and auditory stimuli and less able to maintain eye contact than female newborns. Male newborns also have greater difficulty maintaining affective regulation; they display more irritability, crying, facial grimacing, lability of emotional states, and rapid buildup of arousal. During infancy and toddler years, there is some evidence that males exhibit more irritability and anger, and girls more fearfulness (Ruble & Martin, 1998). From very early on girls smile more than boys. By the 2nd year of life, girls are more empathic and prosocial (Zahn-Waxler, Robinson, & Emde, 1992). Two-year-old girls show more affective discomfort and remorse after transgression (Cummings, Hollenbeck, Iannotti, Radke-Yarrow, & Zahn-Waxler, 1986; Kochanska, DeVet, Goldman, Murray, & Putnam, 1994), and their anger is more likely to be linked to feelings of guilt and shame (Zahn-Waxler & Robinson, 1995). Preschool girls are better at affective perspective-taking than boys, showing greater understanding of others' problems (Denham, McKinley, Couchard, & Holt, 1990). These differences continue throughout childhood and adolescence.

Young girls are more able than boys to control negative emotions under conditions of disappointment (P. M. Cole, 1986; Saarni, 1984). This may reflect their heightened awareness of others' affective states and sensitivity to the impact of their negative feelings on others. This greater social awareness and sensitivity in girls develops early and is seen at all ages (see review by Brody, 1985; McClure, 2000). By preschool and beyond, boys are more physically active and show more frustration, anger, and dysregulation of emotion than girls (Zahn-Waxler, Schmitz, Fulker, Robinson, & Emde, 1996). Girls use more emotional strategies and ruminate about problems more, in contrast to boys, who use more distraction and aggressive strategies (Nolen-Hoeksema & Girgus, 1994; Zeman & Shipman, 1998). Girls tend to ruminate specifically over things they have done wrong and report more guilt about inconsiderate

behavior than do boys (Bybee, 1998). Boys also are more likely than girls to dissemble sadness (Zeman & Shipman, 1997) as they start to hide these kinds of negative emotions over the course of time. By adolescence, girls report more (and more intense) sadness, shame, and guilt, whereas boys tend to deny these emotions. As girls and boys mature, girls continue to inhibit negative affect and show positive, prosocial emotions relative to boys (Maccoby, 1998, 2002; Zahn-Waxler, 2000), whereas boys continue to show more anger and dysregulated emotion. Girls also become increasingly concerned about reading other people for signs of approval and disapproval.

A recent meta-analytic study of temperament (Else-Quest, Hyde, & Goldsmith, *in press*) found higher levels of effortful control in girls than boys. This included intentional attention shifting, inhibitory control or the ability to control inappropriate behaviors, and perceptual sensitivity or the ability to perceive low-intensity environmental stimuli. Perceptual sensitivity may reflect girls' greater awareness of environmental change. In contrast, boys showed higher levels of some features of surgency. That is, boys were rated higher on activity, high-intensity pleasure, and impulsivity but did not differ from girls on shyness or sociability. A third dimension of temperament, negative affectivity, did not yield sex differences (except for a small effect of greater fearfulness in girls). Negative affectivity consists of anger, frustration, emotional intensity, difficulty, and fear.

Social Development

From very early ages, boys' play themes emphasize action, characterized by attention to objects (e.g., tools, inanimate mechanical objects, constructing), action (e.g., rough-and-tumble play, action hero play), and personal achievement and power. In contrast, girls engage in play with relationship and family themes and incorporate objects into relationship-oriented fantasy (Geary, 2002; Maccoby, 2002; Nicolopoulou, 1997). By preschool and middle childhood, children are much more likely to play with same-sex than opposite-sex peers, likely because of shared interests and play styles (Maccoby, 1998). Boys engage in more public play in large groups and in higher levels of physical aggression than girls (Coie & Dodge, 1998; Maccoby, 1990). Boys tend to issue direct commands and establish dominance physically.

Aggression has been typically defined as behaviors that are intended to hurt or harm others. For many years, research focused on physical aggression (i.e., hitting, pushing, punching, kicking, biting, and attacking the property

of others), which is much more common in boys than girls (for reviews, see Coie & Dodge, 1998; Maccoby & Jacklin, 1974; Ruble & Martin, 1998). Boys also typically show more direct forms of verbal aggression than girls, by teasing and insulting others. As noted by Maccoby (2004, p. 9), "Simply put, it has been quite clearly established that males are the more confrontational sex." This sex difference begins in the preschool years, is most pronounced between the ages of 3 and 7, and continues throughout development (Coie & Dodge, 1998). As boys make progress in impulse control they are less likely to anger quickly and hit others. Also, as they become more muscular and able to inflict serious bodily harm, physical fighting becomes more aversive and less frequent. This drop-off begins earlier for girls (Maccoby, 2004) and is probably linked to their earlier facility with language and impulse control. These sex differences are also present in 5- to 7-year-old children's mental representations of physical aggression (Zahn-Waxler et al., 2005).

Recently, more attention has been paid to forms of aggression that inflict harm through threats or damage to relationships. It has been suggested that the claim for greater male aggression is based on too narrow a definition that focuses primarily on the physical and in-your-face verbal aspects. Individuals can also hurt others by ignoring them, excluding them from desired social activities, gossiping about them, and alienating their friends. These often more subtle forms of aggression have been studied under the rubric of relational aggression, indirect aggression, or social aggression (Cairns, Cairns, Neckerman, Ferguson, & Gariepy, 1989; Crick, 1997; Crick & Grotpeter, 1995; Galen & Underwood, 1997; Lagerspetz, Bjorkqvist, & Peltonen, 1988; Underwood, 2003). Most of what is known about these forms of aggression comes from the literature on relational aggression, which involves acts such as threatening to end a friendship or using "the silent treatment" to control or punish a peer (Crick & Grotpeter, 1995). Although some mixed findings have been obtained showing either no sex differences or boys being higher on relational aggression (e.g., David & Kistner, 2000; C. H. Hart, Nelson, Robinson, Olson, & McNeilly-Choque, 1998; NICHD Early Child Care Research Network, 2004; Tomada & Schneider, 1997), the majority of studies have demonstrated that girls are more relationally aggressive than boys (Crick & Zahn-Waxler, 2003), particularly when observational techniques have been used to assess aggression (Ostrov & Keating, 2004; Ostrov, Woods, Jansen, Casas, & Crick, 2004).

Girls and boys differ on other important qualities of their social lives (Eisenberg & Fabes, 1998; Maccoby,

1990). Girls spend more time indoors, interact in smaller groups, have one or two best friends, and engage in more turn-taking and prosocial behavior than boys. Girls attempt to influence each other with compliments, requests for advice, or imitation. These differences affect the interactions of girls with boys. Preschool girls have difficulty influencing boys, although boys do not have difficulty influencing girls (Serbin, Sprafkin, Elman, & Doyle, 1982). Thus, the spheres of influence for girls and boys differ, and girls may have less impact than boys in group settings. Girls' focus on relationships continues throughout childhood and adolescence (Maccoby, 2002; Crick & Zahn-Waxler, 2003). Their social interactions are more likely than boys' to be characterized by cooperation and harmony and themes of relationships and family. This more cooperative, polite, and other-focused interaction style may disadvantage females in mixed-sex groups.

Subjective Well-Being and Self-Esteem

Males tend to experience higher levels of well-being than females. Several meta-analyses and reviews of studies conducted since 1984 have found significant but small effects sizes indicating higher self-esteem in males than females, particularly beginning in adolescence (Harter, 1993; Ruble & Martin, 1998). Some research indicates that self-esteem decreases in females but not in males during adolescence, and that it may actually become enhanced during this period for males (Block & Robins, 1993). During adolescence, girls have more appearance and weight concerns that are part of low self-esteem, whereas boys report more positive aspects of the self, such as self-confidence and success expectations (Ruble & Martin, 1998).

Sex Roles and Sex-Role Stereotypes

The sex differences described are consistent with sex-role stereotypes. These differences often are not large in magnitude and are likely to characterize subsets of males and females who may often fall at the tail ends of the distributions. These individuals, however, contribute to the formation and maintenance of stereotypes and also may be overrepresented in disorders associated with male or female qualities. Adult measures of feminine sex-role traits typically include items that reflect a caring orientation (e.g., "compassionate," "understanding," "sensitive to others' needs") and an immature, submissive style (e.g., "child-like," "gullible," "soft-spoken"; Bem, 1978). Traits associated with masculine sex role mainly reflect qualities of competence and achievement (e.g., "assertive," "athletic,"

"a leader," "self-reliant," "forceful"). Masculine items for children's stereotypes include "active," "careless," and "aggressive," and feminine items include "gentle," "polite," and "sad" (Alfieri, Ruble, & Higgins, 1996). Sex stereotypes begin early. By preschool, boys and girls view anger as a male trait and sadness as a female trait (Karbon, Fabes, Carlo, & Martin, 1992). These children also believe that males lack the capacity to feel sad.

Girls characterized by the feminine ideal or stereotype are described as dependent, relationship-driven, emotional, helpless, passive, and self-sacrificing (Aube, Fichman, Saltaris, & Koestner, 2000; B. I. Hart & Thompson, 1996; Hill & Lynch, 1983; Wichstrom, 1999). These patterns are consistent with internalizing symptoms. Boys characterized by the masculine ideal are described as independent, self-driven, rational, active, and self-enhancing. On the face of it, the male qualities are more positive than the female qualities. However, extremes of more masculine behaviors also pose risk. Even in normative samples, males score higher than females on autistic features and psychopathic traits (Baron-Cohen, 2002; Hamburger, Lilienfeld, & Hogben, 1996).

The studies we have reviewed on sex differences and sex stereotypes were based mainly on normative samples, in the sense that psychopathology was not a focus. However, it seems clear that many, if not most, of the differences identified are potentially relevant to the nature of psychiatric and psychological problems in males and females. Most studies of sex differences in the domains reviewed do not screen for symptoms. So it is entirely possible that some of the sex differences thought to be normative may, in fact, also reflect individuals at the extremes who are already troubled or who have propensities toward problems that may become more full blown in certain contexts.

Next we summarize aspects of socialization that may affect developmental outcomes for males and females. Here, too, much of the research is based on unscreened and presumed (but not demonstrated) normative samples.

DIFFERENTIAL TREATMENT

All cultures create abundant and redundant opportunities for social learning, development, and change in children. In addition to parents as socialization figures, there are siblings, other relatives, peers, teachers, institutions, subcultures, and society as a whole. Initially, influence centers in the family. But soon, most children enter nursery school, day care, and then elementary school, where they experience additional environmental influences. Messages about

societal expectations for appropriate male and female behavior also reach children early in life, through television, books, and movies. We focus here primarily on the parent-child relationship because this is where research on sex differences has centered, noting also the importance of these other areas for understanding differences in adaptive and maladaptive development.

General Features of Socialization

Socialization has been conceptualized and measured at both microscopic and macroscopic levels, with many gradations in between. Parental cognitions reflected in expectations, attitudes, and attributions about different behaviors in girls and boys may create biases and diatheses toward gender-differentiated patterns. For example, parental preferences for male over female infants (Cowan, Cowan, & Kerig, 1993) suggests a higher regard for males that, in turn, may be reflected in better self-concept in boys than girls later in development. General discipline and control practices also may differ (e.g., authoritarian, authoritative, and permissive styles; physical control versus psychological control), as may more specific techniques and practices (e.g., monitoring, love withdrawal, spanking). Parenting has been conceptualized as well in terms of the affective relationship with the child (e.g., nurturant versus rejecting) and quality of attachment (e.g., secure, insecure, disorganized). Forms of child maltreatment (physical abuse, sexual abuse, neglect) can be construed as global negative environmental factors. Parental psychopathology (e.g., depression, Schizophrenia) creates atypical environmental contexts. Another factor concerns the quality of the relationship between the parents. Marital discord and anger are risk factors, as are single parenthood, poverty, and violent neighborhoods.

These aspects of socialization are environmental processes; that is, they reflect constellations of affective, behavioral, and cognitive stimuli that impinge on the child, both directly and indirectly. At the same time, many are embedded in parental characteristics that reflect dispositions and are partly determined by genetic factors. For example, parental depression can create a palpable climate of chronic distress and despair. Depression is also a disorder that is heritable to some degree. Moreover, these conditions can interact with child dispositions that also have some biological bases. It is possible that there are both similarities and differences in how these parent-associated environmental influences affect the development of boys and girls.

Next we consider some of the ways that (presumed) normative parenting processes can inform us about sex differ-

ences in children and adolescents. Other, more global, often negative aspects of the environment (e.g., parental psychopathology, parental conflict, maltreatment) are reviewed in subsequent sections relevant to psychopathology.

Socialization of Sex Differences

Parents treat boys and girls differently in terms of the behaviors mothers and fathers model, the kinds of training and instruction they use, the opportunities and resources they provide, and the ways they monitor and manage their children's activities (Leaper, 2002). These differences are implicated in the development of male and female sex roles and may also be relevant to the quality of interpersonal functioning. Studies often find bidirectional influences, beginning in infancy. For example, mothers are more likely to respond contingently to emotional displays from infant sons than daughters. This may reflect, in part, higher levels of negativity and difficulty regulating emotions in sons; mothers may be making an extra effort to calm and regulate their sons. As another example, mothers talk more to young daughters than sons, partly because the verbal skills of daughters are more advanced. In both instances, the mothers respond differently to boys and girls with respect to their emotions and language in ways that become habitual and possibly influential patterns of communication. Leaper has suggested that if negative emotionality is more prevalent among infant and toddler boys than girls, parents may distance themselves from sons in ways that encourage more independent problem solving. Conversely, girls' more advanced verbal skills may elicit more active involvement from parents in ways that lead to more interdependent social learning.

The quality of the attachment relationship predicts different patterns of adjustment for preschool boys and girls (Turner, 1991). Compared with securely attached children, insecurely attached preschool boys were more aggressive and disruptive, whereas insecurely attached preschool girls were more dependent and showed more positive expressive behavior. Parents are more likely to foster autonomy in their sons than daughters; they also show more physical affection to daughters than sons, in ways that are likely to foster interpersonal closeness (Leaper, 2002). Another way emotional closeness may be encouraged is through discussions of emotional experiences. Several studies indicate that parents discuss more emotional experiences and use more frequent and varied emotional words with their daughters than sons (Leaper, 2002). The emotions discussed also differ depending on the sex of the child, with sadness discussed more often with girls and anger more

often with boys. Anger is a self-assertive emotion, consistent with the traditional masculine role. Sadness is more passive and inner-directed, consistent with the feminine sex role. With boys, parents more often emphasize the causes and consequences of emotions; with girls, they emphasize the experience itself (Cervantes & Callanan, 1998; Fivush, 1989). Parents also expect young girls to have more intropunitive negative emotions (sadness, guilt, fear) and boys to have more extrapunitive negative emotions (anger; Brody & Hall, 1993). Although most research is correlational in design, there are some longitudinal studies indicating that parenting predicts later outcomes in children's social and emotional development (Chaplin, Cole, & Zahn-Waxler, 2005; Leaper, 2002). Chaplin et al. found that fathers, in particular, engaged in sex-stereotyped treatment, responding more to girls' submissive emotions and more to boys' disharmonious emotions. Moreover, parental attention to submissive emotions at preschool age predicted submissive emotions 2 years later.

Parents encourage gender-typed play in many different ways. Of particular interest is how parents handle physical play. Parents may actually discourage physical play in their daughters relative to sons (Fagot, 1978). Parents may contribute to sex differences in activity levels, fathers in particular, by engaging sons in stimulating, physical play, hence amplifying existing sex differences in activity levels. At the most simple level, the sex-typed toys given to boys and girls assure that most of their childhood play will involve enacting and practicing the different roles and activities they will assume as men and women. Mother-daughter dyads are especially likely to engage in sociodramatic play that involves domestic roles and collaborative activities. This could create preferences and skills for feminine-stereotyped affiliative activities (Leaper, 2002). Conversely, fathers' play with sons is more likely to be task-oriented (e.g., putting together a train set) or sports-oriented. Later in childhood and in adolescence, there is evidence for gender intensification as additional social influences are brought to bear on boys and girls going through dramatic biological changes (see review by Leaper, 2002).

It has been said that girls are more often socialized in ways that interfere with self-actualization, that is, to be dependent, compliant, and unassertive (Kavanagh & Hops, 1994). From a young age, girls are perceived as being more fragile and dependent and are therefore more protected and socialized to be dependent on interpersonal relationships (Gurian, 1987; Hill & Lynch, 1983). It might also be said that males are often socialized in a way that interferes with

their development of interpersonal relationships. In combination, a number of observational studies of young children provide support for these ideas. Preschool girls asked to explain why they succeed or fail on performance tasks express more self-derogation, whereas boys give more self-enhancing explanations (Burgner & Hewstone, 1993). This may reflect different parental socialization practices around achievement issues. In a study by Alessandri and Lewis (1993), 3-year-old girls achieved as much as boys but received more negative evaluations and less praise and attention from their middle-class parents for similar accomplishments. Shyness and dependency are treated more positively in females than males, which may help to confirm females' anxiety and uncertainty (Simpson & Stevenson-Hinde, 1985).

Mothers more often show disapproval by frowning when their infant daughters display anger, but support the expression of anger in male infants with looks of empathic concern (Malatesta & Haviland, 1982). Mothers more often accept anger and retaliation as an appropriate response to another's anger in their 2- to 3-year-old sons, but encourage their daughters to resolve anger by reestablishing the damaged relationship (Fivush, 1989, 1991). Mothers of 2-year-olds require their girls more than boys to relinquish toys to guests (Ross, Tesla, Kenyon, & Lollis, 1990). This may contribute to daughters feeling less entitled and ultimately being less likely to try to keep things that they want. Parents of 3-year-olds are more likely to override and negate the verbal assertions of their daughters than those of their sons (Kerig, Cowan, & Cowan, 1993). Mothers of 2-year-olds more often reason with their daughters than sons, pointing out the harmful consequences for others of their aggression (Smetana, 1989). Mothers appear to show greater authenticity in their expressions of anger toward preschool daughters than sons (P. M. Cole, Teti, & Zahn-Waxler, 2003).

Summary reviews of the child-rearing literature indicate some other ways in which parents treat their boys and girls differently. Parents are reported to discourage exploration of the physical environment more often in girls than boys (Siegal, 1987). Parents use more power-assertive discipline and physical punishment with boys than girls (Lytton & Romney, 1991). Discouragement of exploration by girls also limits their opportunities to deviate and heightens exposure to the socializing influences of the family environment. The power-oriented approaches more often used with boys have sometimes been equated with harsher treatment of boys. However, parents may be harder on girls in other ways, including greater pressure to *anticipate* the conse-

quences of their negative acts, rather than, as with boys, reacting after consequences have occurred. This capacity to anticipate (cognitively and affectively), and then refrain from doing harm, is central to the internalization of responsibility and the development of conscience.

Cumulatively, the socialization research indicates that parents are more restrictive and demanding of mature interpersonal behavior in girls, but are more tolerant of anger, assertiveness, misbehavior, and mistakes in boys. In the extreme, this could encourage or exacerbate different problems in boys and girls over the course of development. Also worth noting is that most of the research on parenting is actually research on mothering. Some studies show that fathers make independent contributions to the socialization of their offspring (e.g., Denham et al., 2000). Several studies indicate that fathers engage in more differential treatment of their sons and daughters than mothers do (Siegal, 1987), indicating that fathers may play an important role in the adaptive and maladaptive development of their children.

PERVASIVE DEVELOPMENTAL DISORDERS

Autism, Pervasive Developmental Disorders (or Autism Spectrum Disorders, PDD) is a family of disorders characterized by deficits in three domains, resulting in social impairment, communication abnormalities, and stereotyped behaviors (American Psychiatric Association, 2000). Autism usually is diagnosed by age 3, but parents frequently report concerns as early as the 1st year of life. Autism is distinguished from other PDD primarily by the age at which symptoms begin, symptom severity, and mental impairment. Other PDD or Autism Spectrum Disorders include Childhood Disintegration Disorder (where normal development is followed by the emergence of autistic symptoms), Asperger's Disorder (where language is preserved), Rett's Disorder (which primarily affects females and is linked to a genetic abnormality), and childhood Schizophrenia. The distinct categorization of Asperger's is of some debate (Volkmar, Lord, Bailey, Schultz, & Klin, 2004). Autism and Schizophrenia are considered in greater detail next.

Autism

The prevalence of Autism was reported as 2 to 5 cases per 10,000 in the *DSM-IV* (American Psychiatric Association, 2000), with rates showing an increase over the past few decades (Volkmar, Szatmari, & Sparrow, 1993). The sex

difference in Autism and PDD is quite pronounced. Estimates of the ratio of males to females range from 2:1 to 16:1 (Koenig & Tsatsanis, 2005), although general consensus is that the ratio lies between 4:1 and 7:1 (Rutter et al., 2003; Volkmar et al., 2004). If some aspects of Autism look different in girls, those girls may not be diagnosed equally with males of similar functioning (Koenig & Tsatsanis, 2005). Estimating the sex ratio of Autism is also complicated by the fact that the ratios change as a function of IQ (Volkmar et al., 1993). At low IQs, the sex ratio is 2:1 or 3:1, but at higher IQs, substantially more males than females are affected, with some sex ratio estimates as high as 27:1. Exploration of the etiology of Autism has frequently considered sex differences to be central (Bailey, Phillips, & Rutter, 1996). Biological explanations emphasize genetic, hormonal, and neurocircuitry differences, and social-cognitive explanations emphasize theory of mind, social recognition, and social-emotional sensitivity.

Autism may be comorbid with Schizophrenia later in life (American Psychiatric Association, 2000). It is also frequently comorbid with mental retardation (about 75% of cases). In adolescence, Autism is sometimes comorbid with Obsessive-Compulsive Disorder (OCD), and autistic adolescent girls may respond to pharmacological treatment of OCD better than boys (Koenig & Tsatsanis, 2005). Comorbidity with depression and anxiety is also noted in adolescents (American Psychiatric Association, 2000), particularly higher-functioning adolescents and autistic females. This may result, in part, from being socially ostracized due to atypical social functioning in autistic individuals (Koenig & Tsatsanis, 2005).

Genetic/Biological Explanations

Autism appears largely genetic in origin. Concordance for MZ twins is very high, yielding heritability estimates of approximately 91% to 93% (Bailey et al., 1995). Subsets of Autism Spectrum Disorders, such as Rett's Disorder, are caused by genetic anomalies (Volkmar et al., 2004). Individuals with genetic disorders such as Turner's syndrome, where females are born with one X chromosome, frequently display autistic symptoms (Skuse et al., 1997). These girls are more likely to express autistic symptoms when the X chromosome is maternal rather than paternal. Skuse (1999, 2000) has postulated that genetic imprinting of the X chromosome can explain the heritability of Autism and other PDD. Briefly, the X chromosome in male offspring is necessarily of maternal origin, whereas females have both a maternal and a paternal X. The paternal

X is hypothesized to have a protective locus against Autism, which the maternal X lacks. As noted earlier, normal males are lower than females on social skills and emotion regulation. Genetic risk, combined with the absence of the protective paternal X (and more limited social-emotional capacities), more often places males below the autistic threshold.

Genetic imprinting may also be implicated in sexual dimorphisms of the HPG axis (Lopez, Merchenthaler, Liposits, & Negro-Vilar, 1996). Hormones are thought to play a role, with pre- and postnatal testosterone exposure increasing risk for Autism (Koenig & Tsatsanis, 2005). Individuals with Autism have high testosterone levels and show early signs of puberty (Baron-Cohen, 2002). Another model suggests that oxytocin (lower in males than females) and vasopressin (higher in males than females) are involved in the pathogenesis of Autism (Insel, O'Brien, & Leckman, 1999), although there is no animal model of Autism and human studies have not yet been done. Nevertheless, sex differences in gonadal steroids, oxytocin, and vasopressin are in the direction predicted by the sex ratio in Autism.

Genetic and hormonal factors that play a role in Autism may help lead to differences in neural circuitry and function. The brain is enlarged in autistic individuals, especially toddlers, with particular structural abnormalities in the medial temporal lobe, cerebellum, fusiform face area, and amygdala (Volkmar et al., 2004). Functional MRI studies also show hypoarousal in social brain areas. Interestingly, individuals with Williams syndrome, a neurogenetic disorder characterized by augmented emotion and face processing, show nearly opposite patterns of brain structure (Reiss et al., 2004). It is notable that many of the areas affected in Autism are linked directly with processing social and emotional information, functions clearly impaired in Autism.

The Extreme Male Brain Theory of Autism

Baron-Cohen (2002; Baron-Cohen, Richler, Bisarya, Golan, & Wheelwright, 2003) postulated that Autism is the extreme form of the male brain. Sex differences in Autism reflect the extreme ends of the sex dimorphism in functions of empathizing and systematizing. Other models similarly postulate that sex differences in Autism reflect the underlying sex dimorphisms in social and communication abilities (see Koenig & Tsatsanis, 2005; Volkmar et al., 2004).

Although both systematizing and empathizing are present in both sexes, males do show relatively more systematizing and interest in inanimate objects, and females show more interest in the interpersonal, social realm. Frequent

interests and behaviors that occur among children with Autism and Asperger's syndrome (e.g., attention to detail, collecting, interest in mathematics, mechanical knowledge, scientific and technical information) are presumed to represent an extreme on the systematizing dimension of the male brain and a relative absence of empathizing (e.g., perspective taking, empathy, eye contact, communication; Baron-Cohen et al., 2003; Baron-Cohen & Wheelwright, 2004). Although biological explanations are likely, for example, differences in protective hormonal or genetic complements (Insel et al., 1999; Koenig & Tsatsanis, 2005; Skuse, 2000) or in brain structure, function, and circuitry, the evidence is based mainly on outward expressions of extremes in normative sex differences. Boys are at higher risk for Autism, but the social ramifications may be particularly challenging for girls, who may be more ostracized for displaying autistic symptoms because it is atypical for their sex (Koenig & Tsatsanis, 2005). This may lead to heightened comorbidity with anxiety and depression, especially as girls reach adolescence.

Schizophrenia

Schizophrenia has been divided into two classes of symptoms. Positive symptoms reflect an exaggeration of normal functions, such as disorganized speech, delusions, and hallucinations; negative symptoms reflect a blunting of normal functions, such as flat affect, alogia, and avolition (American Psychiatric Association, 2000). Lifetime prevalence of Schizophrenia lies between 0.5% and 1.0% of the total population, with roughly equal proportions of males and females; however, this equality is complicated by sampling biases. Males more often undergo involuntary treatment and females more often undergo voluntary treatment (Walker & Lewine, 1993).

Compared to females, males have an earlier age of onset by 5 to 6 years (Nasser, Walders, & Jenkins, 2002); are more likely to have an insidious onset (Alaghband-Rad, Hamburger, Giedd, Frazier, & Rapoport, 1997); and have a more chronic course and respond less well to drug treatments (American Psychiatric Association, 2000; Gruzeli, 1994). The common symptoms in males and females complicate the generalization that males have more severe symptoms. Whereas females score higher than males on the unreality syndrome, males are more likely to express negative symptoms and to have hemispheric imbalances related to the active and withdrawn syndromes (Gruzeli, 1994). Another complication is that the severity of Schizophrenia symptoms may interact with age (Seeman, 2002). In young cohorts, males often appear more impaired. This may be

due in part to females having a longer duration of high functioning because they benefit from the networks and premorbid competence established before symptom onset.

Genetic/Biological Explanations

Schizophrenia is highly genetic, with stable heritability estimates over 80% (Cannon, Kaprio, Lonnqvist, Huttunen, & Koskenvuo, 1998), and there do not appear to be sex differences in heritability estimates. Sex hormones have been implicated as potential mechanisms behind sex differences in the expression of Schizophrenia. Sex hormones exert protective effects against Schizophrenia, so females' later age of onset may be derived from high-circulating estrogens in adolescent females. Females are also protected from Schizophrenia symptoms while pregnant, but then are at high postpartum risk. The absorption, metabolism, and clearance of neuroleptic medications vary across the menstrual cycle. Near- and postmenopausal drops in sex steroids may explain the poor functioning evident in midlife and older schizophrenic females (Seeman, 2002). Schizophrenic males are more likely than schizophrenic females to have a history of childhood brain injury. Obstetric complications may also influence the etiology of Schizophrenia, including childhood-onset Schizophrenia in males more than females (Alaghband-Rad et al., 1997; Walker, Walder, Lewine, & Loewy, 2002).

Developmental Precursors

Other sex differences in the etiology and expression of Schizophrenia have been observed. For example, Walker and colleagues (Walker, Grimes, Davis, & Smith, 1993) used home videos to explore whether affect in childhood in individuals who later developed Schizophrenia was different from their unaffected siblings'. They found that preschizophrenic females expressed less joy throughout infancy and adolescence; this finding in males was not as consistent. In a comprehensive review, Walker and colleagues (2002) conclude that there are clear sex differences in premorbid childhood behavior, with males being more noncompliant, inappropriate, abrasive, moody, and disagreeable and females being overly inhibited, sensitive, conforming, withdrawn, and anhedonic. These differences in premorbid behaviors were evident in infancy and increased throughout childhood and adolescence. This is another example of extremes of normative sex differences observed in childhood and adolescence.

The aforementioned sex differences may reflect early signs of different trade-offs for schizophrenic males and females. While adult females with Schizophrenia may be more likely than male schizophrenics to be married, have

children, and attain a higher education, they are also more likely to report marital stress, strained family relationships, and deteriorating social and financial networks (Nasser et al., 2002). Research on sex differences in the etiology of Schizophrenia has been hampered by the original conceptualization of Schizophrenia as a genderless disease (Nasser et al., 2002), because the male:female ratio was often equal. Establishing sex differences in prevalence may be one step toward understanding sex differences in psychopathology (Rutter et al., 2003), yet the Schizophrenia literature illustrates why it is not always a necessary condition. Beneath equal prevalence rates may lie different developmental courses and biopsychosocial risk profiles for males and females (i.e., equifinality).

EXTERNALIZING DISORDERS AND PROBLEMS

Externalizing disorders and problems are reflected in patterns of disturbance that are directed outward and are disruptive to others. In this section we consider Attention-Deficit Hyperactivity disorder, Conduct Disorder, Oppositional Defiant disorder, and related subclinical problems. Substance use is also included given its strong associations with antisocial, disruptive patterns. This decision is somewhat arbitrary given the substantial comorbidity of substance use with anxiety and depression as well.

Attention-Deficit/Hyperactivity Disorder

Two key dimensions, inattention/disorganization and hyperactivity/impulsivity, characterize the symptoms of ADHD. Symptoms must be elevated relative to age-mates, begin in early childhood (prior to age 7), persist over time, and be displayed in a variety of clinically relevant contexts (American Psychiatric Association, 2000). Most of the research has been conducted with males (for a review, see Barkley, 1998).

Estimates of the prevalence of ADHD indicate that boys are three times more likely than girls to be diagnosed with the disorder (American Psychiatric Association, 2000). This estimate comes from research with community samples. Studies targeting clinical samples indicate an even greater preponderance of ADHD among boys (Gaub & Carlson, 1997). Estimates based on clinical samples may be biased by the significantly larger number of boys than girls referred for treatment prior to adolescence. Studies of adolescents and adults have shown that the gender gap in ADHD narrows with age (e.g., P. Cohen et al., 1993).

For many years, diagnostic criteria emphasized the hyperactive aspects of this disorder to the neglect of features that involve inattention. Even though formal diagnostic criteria currently give equal emphasis to both features, the more overt feature of hyperactivity may overshadow the attention problems that are more likely to characterize girls. The *DSM* specification that symptoms must have their onset prior to age 7 also may contribute to the underdetection of ADHD in girls, particularly those who have attention problems as opposed to hyperactivity (Barkley & Biederman, 1997; Nadeau, Littman, & Quinn, 1999).

ADHD is accompanied by many associated impairments in cognition, language, family relations, peer relations, and emotion regulation. In community or nonreferred samples, girls with ADHD appear less impaired than boys in many of these ways. In clinic samples, however, either boys and girls do not differ or girls sometimes show greater impairment, suggesting that it is only the most severely afflicted girls who are referred (Hinshaw & Blachman, 2005). With respect to comorbidity, boys with ADHD appear to have higher rates of other disruptive disorders than girls. A recent meta-analysis found higher rates of internalizing disorders in girls than boys with ADHD (Gershon, 2002). Longitudinal studies into adolescence and adulthood are needed to examine a possible increase in comorbidity for girls, as their rates of internalizing disorders begin to increase markedly relative to boys. Although boys and girls with ADHD do not differ on learning disabilities, girls show lower intelligence, particularly in clinic samples (Gaub & Carlson, 1997; Gershon, 2002). There also may be higher rates of comorbid substance disorders with ADHD in girls than boys (Biederman et al., 2002; Disney, Elkins, McGue, & Iacono, 1999).

Genetic/Biological Explanations

Most of what is known about the etiology of ADHD comes from research conducted with male children and adolescents. It is one of the most heritable psychiatric disorders, with estimates ranging from .7 to .8 (see Tannock, 1998) and heritability levels comparable for males and females (Rhee, Waldman, Hay, & Levy, 1999). Although familial loading is comparable for the two sexes in some studies, there are hints of greater familial loading of ADHD in biological relatives of females than males (Hinshaw & Blachman, 2005). ADHD is linked to maternal substance use, low birthweight, and other biological factors in both males and females (Hinshaw & Blachman, 2005).

Boys and girls with ADHD show similar levels of deficits in executive functions, for example, in response or-

ganization, planning, and shift setting (Gaub & Carlson, 1997; Gershon, 2002). In terms of neural deficits, measured by structural MRI, Castellanos et al. (2001) found that although both boys and girls with ADHD had smaller total cerebral volumes (around 4%) and were similar on most other measures (Castellanos et al., 2002), some other differences between ADHD and control groups were not as pronounced for girls as for boys. An EEG study (Clarke, Barry, McCarthy, & Selikowitz, 2001) found that group differences between ADHD and control girls were not as large as those between comparable groups of boys.

Environmental Explanations

Environmental factors, including parenting styles, are not thought to cause ADHD, but socialization processes may interact with biological predispositions to influence severity, impairment, and comorbidity (Biederman et al., 1995; Hinshaw, 1999). Hinshaw and Blachman (2005) consider different family processes implicated in the prediction of functioning of boys and girls with ADHD in another setting; specifically, transactional processes may be subtler in nature and mediated through the internal distress (depression) in the mother. Future studies of the role of sex/gender in the etiology, prevalence, and developmental course of this disorder are needed. In particular, well-designed prospective studies of both representative and clinical samples with sufficient power to detect gender effects (main effects and interactions) are an important next step.

Conduct Disorder and Problems

Conduct Disorder (CD) consists of an ongoing pattern of behavior that violates the rights of others or age-appropriate societal norms (American Psychiatric Association, 2000). Diagnostic criteria require demonstration of disruptive behaviors in at least three of the following four areas: aggression to people and animals, destruction of property, deceitfulness or theft, and serious violations of rules or status violations (American Psychiatric Association, 2000). Anti-social behavior also has been studied under the rubric of externalizing problems, which include aggressive and delinquent behaviors (Achenbach, 1991a, 1991b). In this section, we draw both from the literature on CD and from studies of externalizing problems.

Prevalence rates for CD range from less than 1% to greater than 10% in the general population, with substantially higher prevalence rates typically found in males (American Psychiatric Association, 2000; Maughan, Rowe, Messer, Goodman, & Meltzer, 2004). Estimates based on

epidemiological samples in the United Kingdom and the United States range from 2 to 4 boys to each girl, averaged across wide age groups (Moffitt, Caspi, Rutter, & Silva, 2001). This is consistent with males' higher levels of serious criminal behavior, physical violence, and other forms of brutality. Similar sex differences are obtained for other kinds of assessments of antisocial behaviors (Foster, 2005). Although the prevalence rate is substantially lower for girls than boys, it is still a problem for girls, and rates have been increasing in recent years (Putallaz & Bierman, 2004). Physical aggression and CD show continuity over long periods of time (Coie & Dodge, 1998), with prediction sometimes lower for females than males (Zoccolillo, Pickles, Quinton, & Rutter, 1992). Girls show more disparate negative outcomes (Moffitt et al., 2001; Pajer, 1998).

CD is comorbid with other externalizing (e.g., ADHD, substance-related disorders), internalizing (e.g., anxiety, depression), and learning disorders (American Psychiatric Association, 2000; Hinshaw & Anderson, 1996). Compared with boys with CD, girls with CD are at higher risk of developing comorbid internalizing conditions such as anxiety, depression, and somatization (Loeber & Keenan, 1994; Robins, 1986; Zoccolillo, 1993). There are unique implications for females and the next generation. These girls are more likely to become sexually active at a young age, choose antisocial partners, become teenage mothers, and raise children with CD (Serbin et al., 1998). Thus, the same risk factor (i.e., CD) may be predictive of later pathways for females and males in terms of the manner in which their disruptive behavior is manifested across development (multifinality).

Because so much of the work on the etiology, course, and manifestation of CD has focused on males, some have questioned the applicability to females (e.g., Zoccolillo, 1993), particularly given their low levels of physical aggression and crime. Some have proposed sex differences in type of symptoms (Côté, Tremblay, Nagin, Zoccolillo, & Vitaro, 2002) and number of risk factors necessary for CD to occur (e.g., McCabe, Rogers, Yeh, & Hough, 2004). Highly aggressive adolescent females and males do differ in forms of antisocial behavior. Whereas males showed more physical aggression, females showed more status violations and conflicts with authority (Maughan, Pickles, Rowe, Costello, & Angold, 2000). Zoccolillo has suggested that because the base rates of correlates such as aggression and crime are so much lower in females than males, females with CD should be compared to other females who do not have the diagnosis, rather than being compared to males. In his view, more accurate identification of CD in

females may be facilitated both by including symptoms more relevant to female forms of antisocial behavior and by lowering the threshold for problem behavior shown by females. There are a number of important reasons not to create different thresholds for diagnosis of CD in males and females (Moffitt et al., 2001; Zahn-Waxler, 1993). At the same time, there are reasons to support the idea of other criteria that may more accurately capture female forms of acting out.

Developmental Models and Pathways

There is growing consensus on developmental models of CD behavior that include dual pathways (Moffitt, 1993; Patterson, Capaldi, & Bank, 1991). An important contemporary issue concerns whether the same developmental models apply to males and females. This debate is currently reflected in the question of whether childhood-onset and adolescent-onset subtypes (American Psychiatric Association, 2000) apply to both sexes. For males, the two subtypes are distinguishable in terms of their etiology and developmental course. Childhood-onset type is diagnosed in children who meet criteria for CD prior to the age of 10. These children are at increased risk for a severe and persistent course of the disorder, with antisocial behavior that escalates in adolescence and continues into adulthood, sometimes in the form of Antisocial Personality Disorder and related patterns of psychopathy (Cale & Lilienfeld, 2002). Early-onset CD is linked to cognitive and neurological deficits, comorbid ADHD, poor parenting, parental antisocial behavior, and other features of family dysfunction (Moffitt, 1993). Aguilar and colleagues (Aguilar, Sroufe, Egeland, & Carlson, 2000) have stressed the importance of psychosocial factors (e.g., child maltreatment, single-parent home, high levels of life stress) in predicting the onset of life-course-persistent antisocial behaviors.

The extremely low rates of early-onset CD in girls in several early studies, including the epidemiological research of Moffitt et al. (2001), where only six girls were identified (less than 0.6% of their community-based sample), have led to questions about how applicable a childhood-onset type of CD is to females. In a high-risk sample (McCabe et al., 2004), child-onset, as well as adolescent-onset, trajectories emerged among both females and males with CD. Although child-onset type was more frequent among males, half of the females with the disorder had a childhood onset, suggesting that child-onset type is not rare for them. A similar conclusion was reached in another study that includes high-risk samples from four American communities where five times as many early-onset girls

were identified as in the Moffitt et al. research (Conduct Problems Prevention Research Group, 1999, 2002).

Youth with adolescent-onset CD are more likely to stop offending by young adulthood, and the nature of their offenses is often less serious than that of life-course-persistent youth (Moffitt, 1993). Silverthorn and Frick (1999) propose a different developmental course for females. They describe a single “delayed-onset trajectory” for antisocial girls, who are thought to share many of the same risk factors as childhood-onset boys. Moffitt and Caspi (2001), in contrast, propose that both early-onset and adolescent-onset types similarly apply to males and females. However, the ratios of males to females for the two subtypes differ; males predominate for early onset of conduct problems, but this disparity lessens substantially for adolescent-onset problems.

Other epidemiological work has examined differences in prevalence rates associated with age and sex of the child (e.g., P. Cohen et al., 1993; Lahey et al., 2000; Maughan et al., 2004). This work also indicates the need to consider the interaction of both gender and age to understand the development and course of CD. Prevalence rates for males tend to increase quite steadily into adolescence. Rates for females tend to remain quite low until early adolescence, but then grow closer to those of males and continue to increase, all the while remaining lower than rates in males (Maughan et al., 2004). In a sample that ranged in age from 10 to 20 years, P. Cohen et al. again found an overall greater prevalence in males than females across age groups. However, for males, the rates showed a linear decrease from age 10 to age 20, whereas for females, the rates were curvilinear, with CD peaking at age 16 and then dropping back down.

The Role of Physical Aggression in Conduct Problems

Early and persistent physical aggression has been linked concurrently and longitudinally to a variety of negative outcomes, including later externalizing problems and delinquency (see review by the NICHD Early Child Care Research Network, 2004). A recent examination of physical aggression from 2 years to third grade yielded five aggression trajectories, three of which were characterized by at least moderate physical aggression at some point during this time. This study is notable in that it included more than 1,100 children from 10 locations across the United States. Of the two highest aggression groups, one was characterized by moderate physical aggression that remained elevated (another had shown a decline), and the other showed high and stable physical aggression. The higher trajectory groups also showed more problems of other kinds by third

grade, including observed and teacher-reported externalizing problems. Physical aggression tended to remain more stable in the context of family adversity. It was possible to distinguish between normative age-related aggressive behavior and problematic behavior that emerged in early childhood. The large sample size theoretically made it possible to study how developmental processes and risk factors would interact with sex of the child. Although no interactions were detected, just as in the Moffitt et al. (2001) study, the number of girls who show serious physical aggression (i.e., the high and stable group) was too small ($n = 8$) to make meaningful comparisons of boys and girls at the extreme. Even when physical aggression was expressed by girls it was at quite low levels.

Physical aggression is often strongly comorbid with relational aggression, and both are also related to other significant social problems (Crick, 1996; Crick & Grotpeter, 1995; for a review, see Coie & Dodge, 1998) and personality pathology (Crick, Murray-Close, & Woods, in press; Werner & Crick, 1999). Several studies have shown that relational aggression provides unique information about other forms of psychopathology above and beyond physical aggression primarily for girls (e.g., Crick, 1996).

Genetic/Biological Explanations

Twin studies indicate a genetic contribution to conduct problems for both sexes, though the estimates of relative contributions of genetics versus shared environment vary, as does the magnitude of sex differences in heritability (Foster, 2005; Jacobson, Prescott, & Kendler, 2002). The consistent sex differences in overt aggression in animals and humans have led to many studies of the role of hormones that differentiate males and females, particularly testosterone. Testosterone has often (but not invariably) been linked with aggressive and dominant behavior in males, but research with females has been limited, precluding parallel conclusions (Susman & Pajer, 2004). Estrogen (estradiol) may be linked to more dominant and antisocial behavior in girls. It may have direct effects on the brain that influence impulsive or nonreflective behavior. Or the effects may be indirect in terms of early pubertal timing, which is associated with more behavior problems in girls. Adrenal androgens have been linked to aggressive behavior in girls, and this relationship appears to parallel the relationships between testosterone and antisocial behavior in boys (Susman & Pajer, 2004).

Less is known about sexual differentiation of the brain relevant to antisocial behavior compared to differentiation of the reproductive system. Some brain areas that may possibly be relevant to antisocial behavior have been identi-

fied, including the prefrontal cortex, caudate nucleus, limbic system, and other brain areas (Segovia et al., 1999; Susman & Pajer, 2004). Low levels of the neurotransmitter serotonin (5HT) have been associated with aggressive and violent behavior and Antisocial Personality Disorder (see Susman & Pajer, 2004). Although many more studies have been conducted with males than females, there is a growing body of literature with females indicating similar patterns. Notably, although females overall have higher serotonin levels than males, depressed individuals are also known to have low serotonin levels. Of the psychiatric disorders, depression is the one that is most likely to co-occur with CD, especially during adolescence, when rates of depression increase, particularly in girls. Hence, the etiologic links between serotonin, types of problems, and gender are undoubtedly complex and important to parse in future research. With respect to comorbidity, there is also the question of temporal ordering of conduct problems and depression. In the Dunedin Longitudinal Study (Moffitt et al., 2001), depression typically emerged *after* the onset of CD in girls.

Low cortisol levels and low heart rate are indicators of low autonomic nervous system (ANS) arousal. Though there are exceptions, several studies of male children, adolescents, and adults have found that antisocial behavior is linked to low cortisol levels, low heart rate, and low heart rate variability (Lahey, Hart, Pliszka, Applegate, & McBurnett, 1993; Susman & Pajer, 2004). More recent studies of antisocial girls have confirmed this pattern for cortisol (e.g., Fishbein, Dax, Lozovsky, & Jaffe, 1992; Pajer, Gardner, Kirillova, & Vanyukov, 2001; Susman, Dorn, Inoff-Germain, Nottelmann, & Chrousos, 1997). Moreover, girls with low cortisol showed poor executive function, lack of empathy, impulsivity, and aggression (Pajer et al., 2001). Notably, several of these characteristics are more often found in males than females in normative samples. Although many developmental studies do not find sex differences in cortisol levels, sometimes lower levels are seen in boys than girls (Essex, Klein, Cho, & Kalin, 2002), and more frequently the HPA axis is modulated differently in boys and girls. Explanations for low cortisol in antisocial individuals have included dysfunctions of the stress system such as the need for stimulation in low-arousal individuals and/or adaptation to an aversive environment whereby the system has become habituated or canalized due to early high levels of stress (Susman & Pajer, 2004). Low cardiac activity has been linked to antisocial, aggressive behavior in male children, adolescents, and adults, reflecting reduced noradrenergic functioning and a fearless, stimulus-seeking temperament. Boys show

lower heart rate than girls. Little is known about the implications of low cardiac activity for girls, indicating the need for further research.

Environmental Explanations

A number of environmental factors have been implicated in the development of antisocial behavior in both boys and girls (Zahn-Waxler & Polanichka, 2004). Examples include lack of parental warmth, poor supervision, and either overly harsh or overly permissive discipline styles. Parental depression and marital conflict have also been linked to disruptive behavior patterns in offspring. Most studies are not longitudinal, and there are few that consider outcomes separately for males and females. Studies do exist, however that show interactions of etiologic factors with sex of child in ways that affect developmental outcomes. McFadyen-Ketchum, Bates, Dodge, and Pettit (1996) found that mothers' coercive behavior and lack of affection predicted increases in boys' physically aggressive and disruptive behavior from kindergarten to third grade. In contrast, these same maternal behaviors predicted *decreases* in the same behaviors of girls. Similarly, mothers' anger directed toward their preschool children predicted continued conduct problems in elementary school for sons but decreased problems for daughters (P. M. Cole et al., 2003). Research also indicates the importance of paternal discipline and practices in the differential prediction over time of aggression in boys and girls (Crick, 2003).

Other research suggests that the environment can differentially influence boys' and girls' externalizing problems (see Zahn-Waxler & Polanichka, 2004). In a longitudinal study of youth at three time points (Davies & Windle, 1997), family discord played a greater role in the development of conduct problems in girls than in boys. In another longitudinal study (Windle, 1992), stressful life events and low family support predicted problem behaviors for adolescent girls but not boys. Sixth-grade girls also appear to be more sensitive than boys to positive parenting in ways that reduce their antisocial behavior (Griffin, Botvin, Scheier, Diaz, & Miller, 2000).

Although onset of delinquent behaviors can spur later criminal involvement for both boys and girls but in different ways (Tolan & Thomas, 1995), the contribution was small once psychosocial factors were considered. For boys, criminal involvement was best explained by their participation in deviant peer groups. For girls, family factors, school achievement, and acceptance were more important in determining the extent of delinquent patterns. In two large-scale, longitudinal studies (Eron, 1992), males and females responded differently to child-rearing practices in ways

linked to different levels of aggression and differential prediction of aggression over time. Loeber and Stouthamer-Loeber (1986) identified a number of studies that found antisocial girls to be more sensitive to disruptions in the social environment, particularly at home. Because attachment to the home environment is especially strong for girls, stressors and disruptions can substantially affect girls' functioning. Because girls spend more time at home and are monitored more closely by their parents, they may be less susceptible to negative neighborhood influences (Kroneman, Loeber, & Hipwell, 2004).

Adolescent antisocial girls and female criminals may come from family backgrounds that are more dysfunctional than those of antisocial boys (Cloninger & Guze, 1970; Henggeler, Edwards, & Borduin, 1987). For example, mother-adolescent dyads and parents in families of female delinquents had higher rates of conflict than their counterparts in families of male delinquents. Moreover, fathers of female delinquents were more neurotic than the fathers of male delinquents. Parental psychopathology is more common for females than males with conduct problems, and maternal contributions to the perpetuation of deviance in female delinquents have been described (Lewis et al., 1991). Female delinquents more often come from violent, abusive homes than do males (Lewis et al., 1991). Often, they become enmeshed in violent relationships with men, perpetuating family traditions of violence and showing child abuse and neglect. Highly aggressive girls experience more family adversity than males (Maughan et al., 2000). Conduct problems are found in both females and males with a childhood history of sexual abuse (Kendall-Tackett, Williams, & Finkelhor, 1993).

Biosocial Explanations

Evidence of biosocial interactions was identified in an all-male sample of adolescents (Rowe, Maughan, Worthman, Costello, & Angold, 2004). Testosterone was related to CD symptoms in boys with deviant peers and to leadership in boys with nondeviant peers. Similarly, work has shown an interaction between pubertal timing and school context on delinquency in girls, whereby early-maturing girls in mixed-sex school settings who were exposed to older peers were at the greatest risk (Caspi, Lynam, Moffitt, & Silva, 1993). Early maturers from an all-girls' school, in contrast, were more protected because they had little exposure to the reinforcements and opportunities for delinquency that older peers provide. It remains to be determined whether similar interactions are present for the opposite sex in each of these studies.

Although both biological and environmental processes may influence the etiology and course of antisocial behavior similarly in females and males, there are also many examples of different processes. The issue is further complicated by the fact that biological and environmental processes are continually interactive and not fully separable. This makes it difficult to study the development, progression, and remission of antisocial behaviors in ways that are meaningful for both females and males. However, evidence continues to accumulate requiring that we pay much closer attention to these issues in our theories and research designs.

Oppositional Defiant Disorder

The essential feature of Oppositional Defiant Disorder (ODD) is a recurrent and persistent pattern of negativistic, defiant, disobedient, and hostile behavior toward authority figures (American Psychiatric Association, 2000). Symptoms of ODD include short temper, purposely annoying others, blaming others for mistakes, oppositional behavior, and noncompliance.

Prevalence rates for ODD range from 2% to 16% across studies. Some studies have shown no sex differences (e.g., Lahey et al., 2000; Lumley, McNeil, Herschell, & Bahl, 2002); however, when differences have been found, males tend to show a higher prevalence (e.g., Carlson, Tamm, & Gaub, 1997; Maughan et al., 2004). Compared to CD, the sex differences are quite small and often nonexistent. This is consistent with the idea that ODD is a less serious form of CD that is expressed to a great extent within the family context, where other interpersonal dynamics may make it easier for girls to express oppositional behavior.

Biological and Environmental Contributions

Whereas much research has been devoted to biological, psychosocial, and child-specific characteristics related to the etiology of CD (for reviews, see Earls, 1994; Frick & Loney, 1999; Hinshaw & Anderson, 1996), there is little research on ODD. Recently, researchers have begun to examine similarities and differences in the etiology and course of ODD based on the sex of the child. Webster-Stratton (1996) has examined sex differences in oppositional behavior problems in 4- to 7-year-olds in three areas of risk factors: child-specific variables (e.g., difficult temperament, high rate of disruptive behavior), parenting variables (e.g., discipline strategies), and other family variables (e.g., parental discord, parental psychopathology). Boys and girls with an ODD diagnosis were actually quite similar in rat-

ings assessing risk factors in each of these three areas. Only a few sex differences were found: Boys were more physically aggressive with parents, and mothers used more physically negative parenting behaviors with boys than girls. Similarly, in another early childhood sample, Nixon (2002) found relatively few differences between boys and girls diagnosed with ODD in risk factors in the areas of child characteristics, parenting behavior, mother-father relationship, and family risk factors. However, in mother-child interactions, mothers criticized boys more often and boys were less compliant than girls.

Even less is known about sex similarities and differences in the etiology of ODD in middle childhood and adolescence. An increase in prevalence of symptoms among both boys and girls during adolescence may reflect greater strivings toward independence and autonomy that become increasingly common at this time. Much of the research on development and outcomes of ODD in males and females makes use of cross-sectional designs, which do not permit conclusions about changes in individuals in the course of the disorder (Lahey et al., 2000).

Oppositional Defiant Disorder as a Pathway to Conduct Disorder

Although ODD is seen as a milder form of disruptive behavior than CD, it can be a precursor to CD. Hinshaw and Anderson (1996) report that despite the evidence of a pattern in which ODD precedes CD, the majority of these youngsters do not appear to progress to the more severe constellation of antisocial behaviors. Moreover, the progression from less serious oppositional and defiant behaviors to more serious aggression, stealing, and major rule violations may be a form of heterotypic continuity of antisocial functioning (Hinshaw & Anderson, 1996). Research is needed to examine whether developmental patterns differ for males and females, or whether the progression from ODD to CD is more characteristic of boys than girls. A sex difference would be anticipated based on the developmental differences in CD. If so, it will be important to learn more about biological and socialization factors that would help to explain the more frequent progression to more serious antisocial behavior in boys than girls who initially showed similar levels of disruptive behaviors.

When children display symptoms of ODD, the behaviors are not only disturbing to adults in positions of authority (e.g., parents and teachers), but also are aversive to peers, which could contribute to further maladjustment. Carlson et al. (1997) found that children (grades K–5) with ODD diagnoses were ignored more often than control children.

Additionally, girls with ODD diagnoses had more social problems than boys with ODD diagnoses. Other girls may find the oppositional, antisocial behaviors associated with ODD in girls especially disturbing, as they may damage friendship formation and other aspects of peer relations (Webster-Stratton, 1996).

In future work, it will be important to examine whether there are sex differences in how ODD is manifested. There are some suggestions of differences, but this work is still in its early stages. It will also be necessary to keep in mind the influence of setting and reporter in assessments of children's symptoms of ODD. Webster-Stratton (1996) found differences in mothers' and fathers' reports of the same child's symptoms: Fathers reported more internalizing symptoms among girls than boys, whereas mothers reported more externalizing symptoms among boys than girls. Fathers and mothers may have different expectations of their child's behavior based on gender socialization. Teacher reports did not correlate with mother or father reports, thus suggesting some "setting-specificity." This fits with the fact that much of the oppositional behavior that is part of this disorder occurs in the family setting and is directed toward parents.

Substance Use

Substance use disorders include substance abuse, which involves problematic use that results in negative occupational or interpersonal consequences, and substance dependence, which involves problematic use that leads to withdrawal symptoms when use is discontinued (American Psychiatric Association, 2000). Because drug abuse traditionally was considered to be primarily a problem in males, females were rarely studied (Lynch, Roth, & Carroll, 2002). Recent research on drug use/abuse in females indicates numerous sex differences in biological response, correlates and causes, and long-term effects and consequences. Research with children and adolescents has focused mainly on sub-clinical substance use, as opposed to substance use disorder or substance dependence, because these clinical disorders are rare among youth of this age (Chassin & Ritter, 2001). Still, it is a major problem and is also often associated with other serious problems in adolescents, most notably conduct problems and antisocial personality.

Developmental Course

Substance use typically begins during the early adolescent years (Chassin & Ritter, 2001), although it can occur in the elementary years for some children (R. Y. Cohen,

Brownell, & Felix, 1990). Age of onset and frequency of substance use are of particular interest because they are relatively strong predictors of substance use progression (Kandel, Yamaguchi, & Chen, 1992). Studies and theories of substance use in childhood and adolescence have focused primarily on boys (Andrews, 2005). Findings from recent studies highlight some important differences (Andrews, 2005). Boys begin to use substances at a younger age than girls (e.g., Johnson, Arria, Borges, Ialongo, & Anthony, 1995). However, prospective research shows that girls' involvement in substances increases at a faster rate than boys during late childhood and early adolescence (Andrews & Tildesley, 2003; R. Y. Cohen et al., 1990). Some studies have shown that by sixth, seventh, and eighth grades, girls' use of cigarettes, alcohol, and marijuana exceeds that of boys, and girls may become dependent more quickly (Andrews, 2005; Andrews, Tildesley, Duncan, Hops, & Severson, in press). Substance use among 12th graders in the United States has declined since 1975 (Johnston, O'Malley, & Bachman, 2002), but the decrease is larger for boys than girls, leading to few discrepancies in current prevalence rates.

Biological/Genetic Explanations

The psychobiology of smoking suggests that nicotine has antidepressant properties, and chemicals in cigarettes function as MAO inhibitors. Girls often find it more difficult than boys to stop using substances, are more likely to relapse, and sometimes are less responsive to treatment interventions (Latimer, Newcomb, Winters, & Stinchfield, 2000; Lewinsohn, Hops, Roberts, Seeley, & Andrews, 1993). Females are more vulnerable than males to depression and hence may be more likely to relapse to reduce negative affect. Avoidance of weight gain may also be a contributory factor, as females strive for the lean body type that is part of the sociocultural image of a desirable body type. Weight concerns predict initiation of smoking among adolescent girls but not boys (French, Perry, Leon, & Fulkerson, 1994).

Biological models of substance use have focused primarily on heritability and genetic influence (e.g., Crabbe, 2002; McGue, 1994; Prescott, Aggen, & Kendler, 1999; Russell, 1990). Some studies suggest that this association is stronger for males than for females (e.g., Jang, Livesley, & Vernon, 1997), and alcoholism characterized by early onset, violence, and criminality is mainly limited to males (Cloninger, 1987). However, other studies have shown stronger genetic influence for females and shared environmental influences for males (e.g., Prescott et al., 1999). Several investigators have suggested reward-deficiency

pathways of addiction (e.g., through dopaminergic, opioid, serotonergic, and cholinergic receptors) that are common across substances and could have a genetic link (Koob & Le Moal, 2001; Robinson & Berridge, 2000, 2001). Research on biological factors has also targeted early pubertal development as a potential contributor to substance use. Girls who reach puberty earlier than their peers are more likely to use substances such as marijuana and alcohol (e.g., Petersen, Graber, & Sullivan, 1990; Stattin & Magnusson, 1990). Their social experiences with older peers (particularly older boys) may create risk for substance use (Magnusson, Stattin, & Allen, 1985).

The deviance-proneness (Sher, 1991; Zucker, 1994) or problem behavior (Jessor, 1987) model posits that substance abuse is the result of temperamental and personality characteristics associated with externalizing and antisocial behavior patterns. Aggressive behavior, in fact, is one of the most robust, and most widely studied, childhood and adolescent predictors of adolescent and adult substance use, abuse, and disorder (for reviews, see Andrews, 2005; Chassin & Ritter, 2001; Hawkins, Catalano, & Miller, 1992; White & Hansell, 1996; Zucker, Fitzgerald, & Moses, 1995). Antisocial Personality Disorder, which is one of the most frequent *DSM* diagnoses in alcohol and drug abusers, is much more common in males than females. Thus, the deviance-proneness/problem behavior theory may apply more to substance use in boys than girls. Because past research on the deviance proneness model and substance use/abuse has been restricted to aggressive behaviors more typical of boys (Chassin & Ritter, 2001), it hasn't been adequately studied for girls and the forms of aggression more typical for them, such as relational aggression (Chassin & Ritter, 2001).

The negative affect model of the development of substance use is based on the premise that substances are used as self-medication to alleviate negative emotion and reduce emotional stress (Cooper, Frone, Russell, & Mudar, 1995; Sher, 1991; Zucker, 1994). Cross-sectional evidence provides support for the hypothesized link between alleviation of negative feelings and substance use in adolescent samples. For example, adolescent depression is associated with concurrent adolescent drug use, heavy alcohol use, and nicotine dependence (Deykin, Buka, & Zeena, 1992; Fergusson, Lynskey, & Horwood, 1996; Rohde, Lewinsohn, & Seeley, 1996). However, findings from prospective studies have been mixed, with some studies demonstrating links between negative affectivity and future substance use/abuse (e.g., Caspi, Moffitt, Newman, & Silva, 1996; Henry et al., 1993) and others not (e.g., Chassin, Curran, Hussong, & Colder, 1996; Chassin, Pillow, Curran, Molina,

& Barrera, 1993). The negative affect model may be more applicable for girls than for boys (e.g., Andrews, 2005; Chassin, Pitts, & DeLucia, 1999; Rohde et al., 1996). Further research is needed to test this proposition and also to determine whether the deviance-prone model is more applicable to boys.

Past research on negative emotionality has focused on features such as general emotional distress, depressive symptoms, anger, and anxiety (Chassin & Ritter, 2001; Collins & Shirley, 2001). Other aspects of negative affect such as guilt and shame may also be predictive of substance use. These emotions typically are linked to strong feelings of inadequacy and regret that, in some instances, generalize to negative evaluations of the entire self (Tangney, Wagner, Hill-Barlow, Marschall, & Gramzow, 1996). When this happens, some individuals may turn to substance use to alleviate these uncomfortable feelings. Because girls are more likely than boys to experience these negative self-conscious emotions (Zahn-Waxler, 2000), they may be more often susceptible to these processes. Because substances act on the reward system, negative emotions may be replaced temporarily by pleasurable feelings. It would also be useful to separate anger from other negative emotions to determine whether deviance-proneness and negative affect models become more strongly gender-based when anger and hostility are considered separately.

Environmental Explanations

In addition to different types and levels of negative emotions in boys and girls, aspects of their social relationships may influence self-medication. Because girls are more likely to invest in and derive psychologically relevant information about the self and others from interpersonal relationships (Cross & Madson, 1997; Geary, 1998; Leadbeater, Blatt, & Quinlan, 1995; Maccoby, 1990), they may more often experience heightened distress when they encounter interpersonal problems and relational ties are threatened, particularly with friends and romantic partners (Crick & Zahn-Waxler, 2003). For boys, other types of failure experiences may lead to self-medication.

In summary, research on the role of gender in substance use problems provides some evidence for gender-specific pathways and effects of substance use among youth. It will be important to consider the role of parents' substance use, not only in terms of direct effects but also in terms of parental practices and parent-child interactions, for example, their different relationships with sons and daughters (Andrews, 2005). There is also a literature on the role of peer socialization in substance use/abuse that could inform future research on how these environmental

processes may differentially affect boys and girls' substance use and abuse.

INTERNALIZING DISORDERS AND PROBLEMS

Internalizing disorders and problems are reflected in patterns of disturbance that are directed inward and are highly distressing to the individuals afflicted. In this section, we consider mood disorders, anxiety disorders, eating disorders, and related subclinical problems. We also provide a conceptual analysis of the role that early anxiety may play in the later development of depression.

Mood Disorders

The essential feature of Major Depression and Dysthymia is either depressed mood or loss of interest or pleasure in nearly all activities. In children and adolescents, the mood may be irritable rather than sad. Additional symptoms include vegetative signs (e.g., changes in appetite or weight), cognitive signs (e.g., difficulty thinking and concentrating), and emotional signs (e.g., feelings of worthlessness or guilt). Most of the developmental literature is on unipolar depression and dysthymia. Bipolar Disorder is not considered here, as research with children and adolescents is more recent, with little known about sex differences.

Beginning in adolescence, females are two to three times more likely than males to experience unipolar depressive disorders, as seen in both community-based and clinically referred samples (Kessler, McGonagle, Swartz, Blazer, & Nelson, 1993; Nolen-Hoeksema, 1990; Weissman & Klerman, 1977; Weissman, Leaf, Bruce, & Florio, 1988). It is also present whether depression is diagnosed as a disorder or measured along a continuum of symptom severity. In this section, we consider both clinical and subclinical levels of depression.

The rates of depression are low in childhood and comparable for boys and girls (with boys sometimes showing slightly higher rates; Anderson, Williams, McGee, & Silva, 1987; Kashani & Carlson, 1987; Kashani, Holcomb, & Orvaschel, 1986; Poznanski & Mokros, 1994). Prevalence rates increase dramatically during puberty, particularly in girls. Lifetime prevalence of Major Depression in adolescent females is between 20.8% and 31.6% (Kessler et al., 1993; Lewinsohn et al., 1993; Lewinsohn, Rohde, & Seeley, 1998), and the prevalence of subclinical depression is as high as 59% (Roberts, Andrews, Lewinsohn, & Hops, 1990). Lewinsohn, Rohde, et al. estimate that 35% of girls will have had at least one episode of Major Depression by age

19. For boys, rates remain the same or increase to a lesser extent (Anderson et al., 1987; Angold & Rutter, 1992).

Studies based both on diagnostic interviews and standardized self-reports indicate that this change in rates begins around age 13 to 15 (Angold, Costello, & Worthman, 1998; Ge, Lorenz, Conger, Elder, & Simons, 1994; Petersen, Sargiani, & Kennedy, 1991; Wichstrom, 1999). There is a 4% to 23% increase in diagnosed depression in adolescents between the ages of 15 and 18 (Hankin, Abramson, Moffitt, Silva, & McGee, 1998). After puberty, the lifetime prevalence in females is twice that of males (Lewinsohn et al., 1993). Comorbidity of depressive and anxiety disorders is much more common in girls than boys (Lewinsohn, Rohde, & Seeley, 1995); moreover, depression that is comorbid with more than one anxiety disorder is virtually exclusive to females (Lewinsohn, Zinbarg, Seeley, Lewinsohn, & Sack, 1997). Female gender and presence of a coexisting anxiety disorder are also related to severity of initial depression (McCauley et al., 1993). Co-occurrence of symptoms is even higher when subclinical levels are considered. Although depression and anxiety can be clearly differentiated at biological, cognitive, behavioral, and affective levels, the extent to which they overlap and co-occur suggests that the combination represents a unique but common form of depression, particularly in females.

Females show a different constellation of depressive symptoms than males, notably, more anxiety, more somatic symptoms, hypersomnia, weight gain, increased appetite, fatigue, psychomotor retardation, and body image disturbance (see review by Zahn-Waxler, Race, & Duggal, 2005). Increased appetite and weight gain seem to be the most distinct symptoms in women and adolescent girls. Higher rates of crying, sadness, and negative self-concept have been noted for school-age and adolescent girls.

In research by Gjerde (1995) and Gjerde and Block (1996), dysphoric males often expressed their unhappiness directly and without hesitation, by acting on the world in an aggressive, hostile manner. Dysphoric symptoms in female adolescents, in contrast, were characterized by introspection, absence of open hostility, and a mostly hidden preoccupation with self. As early as age 7, boys who later showed Dysthymia were aggressive, self-aggrandizing, and undercontrolled, whereas dysthymic girls were introverted, oversocialized, overcontrolled, anxious, and introspective (Block, Gjerde, & Block, 1991). Young girls who later became depressed also had close relationships. The sadness and anxiety in depressed girls and hostility in depressed boys can be seen as exaggerations of normative sex differences. These studies focus on subclinical depression. Fur-

ther studies of males and females with clinical depression are needed to determine whether their symptomatology shows a similar pattern. Other research suggests that young depressed boys show a pattern of acting out (Kovacs, 1996).

Genetic/Biological Explanations

Some studies report similar heritability estimates for depressive disorders in males and females; several others find differences (e.g., Bierut et al., 1999; Jacobson & Rowe, 1999; Kendler, Gardner, Neale, & Prescott, 2001; Tambs, Harris, & Magnus, 1995). Kendler, Gardner, et al. suggest that in genetic linkage studies, the impact of some loci on risk for Major Depression will vary in men and women. Genetics are also involved in the etiology of depression through their effect on sensitivity to environmental events. Silberg, Rutter, Neale, and Eaves (2001) found that genetics had a larger effect on the development of depression in adolescent girls who had experienced a negative event in the previous year than on those who did not. Kendler and colleagues (Kendler, 1998; Kendler et al., 1995) found that persons at greater genetic risk were twice as likely to develop Major Depression in response to severe stress than those at lower genetic risk. Genetic risk also altered sensitivity to the environment for women only (Kendler et al., 1995). At puberty, girls' negative life events and stability of depression over time are more genetically mediated than for boys (Silberg et al., 1999).

Biological processes have been studied in terms of hormones that increase during puberty, timing of puberty, physical bodily changes, and interactions of body change and weight gain. Angold and colleagues (Angold, Costello, Erklani, & Worthman, 1999; Angold et al., 1998) have examined the influence of hormones and body development on depression. Angold et al. (1998) found that pubertal development (measured by Tanner stages), but not age, accounted for increased rates of depression. Boys showed higher rates of depression than girls before reaching Tanner stage III (the midpoint of puberty, when body changes become apparent but before menarche). Girls showed much higher rates of depression than boys at and after Tanner stage III (Angold et al., 1998). Angold et al. (1999) then examined hormones associated with pubertal development and reproduction. Testosterone and estradiol were more strongly related to depression than Tanner stages. A positive association between estradiol and later depressive affect has been shown even after the course of a year (Paikoff, Brooks-Gunn, & Warren, 1991).

This link between estradiol and depressive affect may seem counterintuitive because estradiol is thought to en-

hance mood, has antidepressant properties, and increases the efficacy of antidepressants (McEwen, 2002). However, variability and changes in estradiol levels also vary as a function of pubertal development, with peaking diurnal variability near the time of menarche (Angold et al., 1999). Given that heightened levels and variability frequently co-occur (i.e., the law of initial values), it is possible that adolescent girls at risk for depression have high levels and, more important, the most variable estradiol levels. It would be valuable in future research on hormones and depression to study these processes during adrenarchy in middle childhood and also to examine the possibly protective function of oxytocin given its role in caregiving and relaxation (Cyranowski, Frank, Young, & Shear, 2000; Frank & Young, 2000).

Early puberty in girls (but not boys) is associated with more depression. Young girls may have not yet acquired coping skills to deal with the pressures and stresses of early physical maturation. Angold et al. (1998) and others did not find an effect of pubertal timing on depression, but several others have found such associations. Girls who reach puberty earlier are more likely to have or to develop depressive symptoms than those who reach puberty on time (e.g., Brooks-Gunn & Warren, 1989; Ge et al., 1996; Graber, Lewinsohn, Seeley, & Brooks-Gunn, 1997; Hayward et al., 1997; Paikoff et al., 1991; Stice, Presnell, & Bearman, 2001). Stice et al. also show that high body mass, body dissatisfaction, and dieting partially mediate the link between early puberty and depression. As early puberty is also linked with antisocial patterns in girls, it is clearly a time of high risk. Early puberty results from a complex mix of biological, social, and contextual factors. Genes, as well as environmental influence like nutrition, exercise, and weight, play a role. Depression in mothers may induce early puberty in daughters (Ellis & Garber, 2000), as well as the presence of unrelated adult male father figures (also see Moffitt, Caspi, Belsky, & Silva, 1992). Animal studies suggest that chemicals known as pheromones produced by unrelated adult males accelerate female pubertal development. Although the vomeronasal organ is vestigial in humans, a similar process may occur for these girls.

Associations between HPA axis functioning and psychopathology may differ for males and females. In adolescents who were normal, depressed, or depressed with comorbid externalizing problems (Klimes-Dougan, Hastings, Granger, Usher, & Zahn-Waxler, 2001), females with depressive symptoms showed a flattened diurnal rhythm. The other groups, in contrast, showed the typical diurnal pattern of high early morning cortisol levels and a marked

decline over the course of the day. Depressed girls also showed a more gradual decline in cortisol following discussion of a conflict. In a longitudinal study of younger children (Smider et al., 2002), girls showed higher cortisol levels than boys at age 4.5 years. For girls only, high cortisol predicted more depression and anxiety a year and a half later. Girls' greater physiological reactivity may reflect early proneness to later internalizing symptoms. In a study of stress responses in adults (Stroud, Salovey, & Epel, 2002), women showed greater cortisol reactions to social rejection challenges, and men showed greater cortisol responses to achievement challenges. Social rejection has been linked to depression.

Environmental Explanations

Parental depression (most often studied in mothers) creates substantial risk for depression in offspring (Beardslee, Versage, & Gladstone, 1998; Davies & Windle, 1997; Downey & Coyne, 1990; Garber, Keiley, & Martin, 2002; Goodman & Gotlib, 1999; Hammen, Burge, Burney, & Adrian, 1990; Hops, 1996). Offspring are at greater risk for depression if both parents are depressed (Birmaher et al., 1996; McCauley, Pavlidis, & Kendell, 2001). The lifetime risk of depression for children with a depressed parent has been estimated at 45% (Hammen et al., 1990). Because depression is heritable, it is commonly assumed that children of depressed parents are at increased risk due to genetic similarity. However, the experiences of these children can differ markedly as well.

Depressed parents are, on average, less reciprocal, attuned, and engaged in interactions with their children as early as infancy. In addition to the sadness that marks depression, depressed parents express a greater range and less control of other negative emotions such as anxiety, guilt, irritability, and hostility than controls. Children exposed to a depressed parent's despair and lack of pleasure in daily activities can come to experience these emotions through contagion and imitation. Depressed parents often model helpless, passive styles of coping. They tend to use discipline methods that are either ineffectual, coercive, or guilt-inducing (Beardslee et al., 1998; Cummings, DeArth-Pendley, Du Rocher Schudlich, & Smith, 2001; Downey & Coyne, 1990; Gelfand & Teti, 1990; Goodman & Gotlib, 1999; Zahn-Waxler, 2000). These conditions would be expected to affect both boys and girls, yet differences are also likely.

In infancy, males may be more vulnerable than females to the socioemotional effects of maternal depression, particularly in situations that involve interactional stress or

challenge (Weinberg, Olson, Beeghly, & Tronick, 2005). Prior studies had suggested that male infants, in general, show greater difficulty than female infants maintaining affective regulation in mother-infant interactions. Typically, this heightens mothers' responsiveness to boys' affective and behavioral displays and helps to maintain greater coordination or synchrony in mother-male than mother-female interactions (Weinberg et al., 1999). However, depressed mothers would be expected to have difficulty maintaining this coordination, hence setting the stage for environmental adversity more likely to be experienced by male than female infants.

In childhood and adolescence, girls of depressed mothers are more susceptible to the influences of maternal depression than are boys with respect to internalizing problems (Boyle & Pickles, 1997; Conger et al., 1993; Cummings et al., 2001; Hops, 1996; Sheeber, Davis, & Hops, 2002). Moreover, the effects of maternal depression on adolescent girls' depression become stronger as girls mature. Longitudinal studies indicate long-term effects of maternal depression on later development of depression in daughters but not sons (Davies & Windle, 1997; Duggal, Carlson, Sroufe, & Egeland, 2001; Fergusson, Horwood, & Lynsky, 1995). In one study, depressive symptoms increased over time in adolescent daughters, but not sons, who provided comfort and suppressed their own aggression (B. Davis, Sheeber, Hops, & Tildesley, 2000). Adolescent girls provide more support to depressed mothers than do sons. They also express more sadness, worry, and withdrawal than sons, as well as responsibility for the mother's depression (Klimes-Dougan & Bolger, 1998). Daughters may be susceptible to their mother's unhappiness because they spend more time with her and have stronger emotional ties than sons (Gurian, 1987). Mothers' modeling of depressive behavior also may be particularly salient to girls and linked to sex roles.

Parental conflict and divorce play a role in children's depression. Depression of a parent can itself lead to marital conflict, and vice versa, and frequently they co-occur (Beardslee et al., 1998; Conger et al., 1993; Cummings et al., 2001; Davies & Windle, 1997; Downey & Coyne, 1990). Marital discord and divorce lead to both internalizing problems (depression, anxiety), for which females generally are at higher risk, and externalizing problems (aggression, antisocial behavior), for which males generally are at higher risk. Parental divorce can influence the development of depression in adolescents through increased family conflicts, financial difficulties, unavailability of parents, less parental warmth and involvement,

and changes in the family (Aseltine, 1996). When exposed to family conflict and discord, adolescent girls are more likely than boys to develop depression and related problems (Aseltine, 1996; Crawford, Cohen, Midlarsky, & Brook, 2001; Dadds, Atkinson, Turner, Blums, & Lendich, 1999; Formoso, Gonzales, & Aiken, 2000; Garnefski, 2000; Vuchinich, Emery, & Cassidy, 1988).

Girls show more interpersonal concern and involvement in family problems (especially involving mothers), which contributes to girls' higher rates of depressed mood than boys (Gore, Aseltine, & Colten, 1993). Davies and Lindsay (2004) have recently reported a similar pattern. For girls only, elevated levels of communion partly accounted for their greater reactivity to conflict between parents and likelihood of internalizing problems. Communion (i.e., interpersonal connectedness and concern) was based on items from a sex-role inventory, such as "I care what happens to others"; "When someone's feelings have been hurt, I try to make him/her feel better." Even prior to adolescence, girls show more fear, emotional distress, and feelings of blame and responsibility than boys (Davies & Lindsay, 2004). Aube et al. (2000) found that unassertive girls who also felt overly responsible for others were more depressed than boys.

Effects of maternal depression and family discord on gender-linked symptoms are also seen very early in development (Essex, Klein, Cho, & Kraemer, 2003; Zahn-Waxler, Iannotti, Cummings, & Denham, 1990). Essex et al. found that boys exposed to maternal depression in infancy had a preponderance of internalizing problems relative to externalizing problems, but if subsequently exposed to marital conflict, the mix toward externalizing problems increased to match levels of clinic-referred children. For girls, the preponderance of internalizing problems increased to match levels of clinic-referred children when initial exposure to marital conflict occurred in the toddler/preschool period. Overall, girls showed more depression and anxiety than boys, which is not often found in community samples of young children. This may reflect differences in instruments, as the Health Behavior Questionnaire items used by Essex et al. are similar to *DSM* symptoms and are not weighted by sex of child. Instruments like the Child Behavior Checklist, in contrast, require that girls endorse more symptoms than boys to achieve the same standardized score.

Less support from one's family, particularly one's mother, is related to more depression and difficulty among adolescents (Aseltine, Gore, & Colten, 1994; Barrerra & Garrison-Jones, 1992; T. Field, Diego, & Sanders, 2001;

Ge et al., 1994; McFarlane, Bellissimo, & Norman, 1995). The impact of familial support and relationships with parents can be particularly great for girls. In one study, conflict with the mother that was associated with submissive coping was related to concurrent depression and predicted increases in these symptoms 1 year later for adolescent daughters but not sons (Powers & Welsh, 1999). Although adolescents who view their parents as very caring are unlikely to develop depression, girls with overprotective fathers show more symptoms (Avison & McAlpine, 1992). Parental overprotection may create a diminished sense of mastery that can lead to depression. The difficulties girls face balancing their need for family support and intimacy with their need for increased autonomy in adolescence may contribute to their higher rates of depression than boys (McGrath, Keita, & Strickland, 1990).

Life Events and Quality of Relationships

Some researchers report that girls and boys are similarly exposed and vulnerable to the effects of stressful life events (Avison & McAlpine, 1992; Gore et al., 1992; Kendler, Thornton, & Prescott, 2001). Others indicate that girls do report more negative events, or that they may experience the same events as more negative than boys (Goodyer, 2001; Gore et al., 1992). Girls tend to show different patterns in the relationship between life events and depression than boys, particularly after puberty (Ge et al., 1994; Silberg et al., 1999). Females are more likely than males to experience or be affected by the stresses of others in addition to their parents, which also would create vulnerability to depression. The timing of major life events also plays a role in the etiology of depression. Adolescents going through multiple life changes simultaneously are at greater risk (Petersen et al., 1991). This is especially true for girls, who are more likely than boys to experience puberty as they make the transition to different, larger, more challenging schools (Simmons, Burgeson, & Carlton-Ford, 1987).

Because girls are more invested than boys in interpersonal relationships with friends and romantic partners (Leadbeater, Kuperminc, Blatt, & Herzog, 1999; Simmons & Blyth, 1987), they are more likely to become depressed when relationships are disrupted or changed, as often happens at adolescence (Cyranowski et al., 2000; Leadbeater et al., 1999). Heightened interpersonal focus and reliance on others are inversely related to agency and instrumentality, which can protect against depression (Allgood-Merten, Lewinsohn, & Hops, 1990; Nolen-Hoeksema & Girgus, 1994). Girls show fewer of these instrumental traits than do boys. Also, popularity is negatively linked to depression in

girls but not boys (Oldenberg & Kerns, 1997). Interpersonal vulnerability may lead to helplessness, fear of abandonment, and a heightened need for intimacy (Leadbeater et al., 1999), creating a cycle and escalation of personal distress.

Distinctions have been made between dependent life events and independent life events. Dependent events are those in which the person contributes to the event through his or her own actions (e.g., breaking up with someone, getting a bad grade). Independent events are not influenced by the person experiencing the event (e.g., death of a relative, a natural disaster). Both types of events can contribute to depression (Kendler, Karkowski, & Prescott, 1999; Williamson, Birmaher, Anderson, Al-Shabbout, & Ryan, 1995). Dependent interpersonal events are closely tied to depression for adolescent girls (Rudolph, 2002). In a longitudinal study of adolescents (Ge et al., 1994), changes in uncontrollable events also predicted increases in girls' but not boys' depression. Moreover, symptom changes were related to change in stressful events only for girls.

Gender-Based Theories of Depression

Cumulatively, these findings on sex differences in correlates and predictors of depression point to the need for gender-based theories. One of the first serious attempts to understand depression in adolescent girls can be found in the gender-intensification hypothesis (Hill & Lynch, 1983). In this view, cultural reinforcement of the feminine ideal or stereotype promotes behaviors that are dependent, relationship-driven, emotional, helpless, passive, and self-sacrificing. These behaviors are hypothesized to create risk for depression. Before puberty, gender roles are more fluid and girls are not expected to adhere to them. At puberty, however, expectations change, and many girls place more emphasis on conforming to the sex roles set out by their culture (Allgood-Merten et al., 1990; Aube et al., 2000; B. I. Hart & Thompson, 1996; Huselid & Cooper, 1994; Wichstrom, 1999). One aspect of conformity concerns lack of self-expression and self-assertion. Harter and colleagues (Harter, Waters, Whitesell, & Kastilic, 1998) found that the "loss of voice" and low self-worth in adolescence, more common to females than males and implicated in depression, is restricted to a subset of girls who endorse a feminine orientation. Loss of voice refers to the display of false self-behavior, including suppression of opinions. Negative views of the self are thought to contribute to the development of depression in girls (Allgood-Merten et al., 1990; Avison & McAlpine, 1992; Block & Gjerde, 1990; Gjerde & Block, 1996; Lewinsohn, Gotlib, Lewinsohn, Seeley, & Allen, 1998). The self-conscious emotions of guilt and shame also

are part of this process. They are linked to depression and are more common in females than males (Zahn-Waxler, Cole, & Barrett, 1991).

Several recent theories have been advanced to explain high rates of depression in adolescent females (Cyranowski et al., 2000; Hankin & Abramson, 2001; Nolen-Hoeksema & Girgus, 1994). Although no current framework can provide a full etiological account of depression in females, these models represent important first efforts to integrate multiple factors that interact to increase girls' risk for depression. Cyranowski et al. proposed that female gender socialization and increased levels of hormones such as oxytocin (which is associated with reproduction and caregiving) at puberty can intensify the need for affiliation in girls. This, in turn, can contribute to a difficult adolescent transition and a depressogenic diathesis. Gender intensification would result from such vulnerabilities as insecure attachments to parents, an anxious or inhibited temperament, and low instrumental coping skills. These factors interact with stressful life events, particularly in the interpersonal domain. More specifically, Cyranowski et al. hypothesize that the increase in interpersonal stressors related to friendship roles and dating during adolescence interacts with girls' increased need for affiliation, making girls more vulnerable to depression following negative interpersonal events.

Hankin and Abramson (2001) proposed a cognitive vulnerability-stress model in which preexisting vulnerabilities (resulting from genetics, personality, and environmental adversity) contribute to cognitive vulnerabilities and the likelihood of experiencing negative events. Over time, repetitions of events, emotions, and attributions that are negative lead to greater depression. This model helps explain the greater depression in girls because girls report more negative affect (neuroticism), experience more negative events such as sexual abuse, and show more cognitive vulnerability in the form of rumination and negative inferential style than boys.

Nolen-Hoeksema and Girgus (1994) advanced three hypotheses: (1) The causes of depression are the same for girls and boys, but become more prevalent for girls in adolescence; (2) there are different causes for depression in girls and boys, and the causes for girls become more prevalent in early adolescence; and (3) girls are more likely than boys to carry risk factors for depression even before early adolescence, but the risk factors lead to depression only in the face of challenges that increase in early adolescence. They looked at risk factors in personality, biology, and social challenges and concluded that model 3 would most likely provide the greatest explanatory power. Although

longitudinal research is needed for definitive conclusions, good candidates for risk factors more common in girls than boys in childhood included low instrumentality, low dominance and aggression, and a tendency to dwell on problems (i.e., ruminative coping, which can increase and prolong negative mood). When such factors combine in adolescence with biological and social challenges faced by girls, depression may ensue. Given multiple causes of adolescent depression, it is unlikely that one model will be sufficient.

We have emphasized explanations for the preponderance of female depression in the adolescent period. Some risk factors may be the same for males and females, and some obviously differ in both biological terms and social consequences, for example, early puberty. More information is needed about sex differences in the expression of depression and risk factors that may be more salient for males.

Following a review of anxiety disorders, we extend gender-based models of depression downward in age to consider developmental precursors. We focus on the confluence of anxiety, rumination, socialization, social sensitivity, and stress reactivity in childhood.

Anxiety Disorders

There are a number of different anxiety disorders experienced by children and adolescents: Panic, Agoraphobia, Specific Phobia, Social Phobia, Posttraumatic Stress, Separation, and Generalized Anxiety. All are characterized by fears and/or anxieties, but they may differ in their form of expression or context depending on the disorder.

Prevalence rates for anxiety disorders have been estimated to be greater than 10% in a large number of epidemiological studies, with some surveys indicating up to 20% of children and adolescents (see Albano & Krain, 2005). An individual anxiety disorder may occur alone, but more often than not they are comorbid with each other and with depression. Anxiety disorders are higher for females than males, beginning in childhood. Girls have more fears and worries than boys and experience them more intensively (Gullone & King, 1993; Ollendick, Yang, Dong, Xia, & Lin, 1995; W. K. Silverman, LaGreca, & Wasserstein, 1995; Spence, 1998). These sex differences in fear and anxiety are present in the 1st years of life at clinical levels (A. S. Carter, Briggs-Gowan, Jones, & Little, 2003) and continue through adolescence (King, Gullone, Tonge, & Ollendick, 1993). Girls develop anxiety disorders faster than boys. By 6 years of age, twice as many girls have developed an anxiety disorder (Lewinsohn, Gotlib, et al., 1998). Given the high comorbidity and common internalizing nature of anxiety and mood disorders, particularly in

girls, there are many parallels in developmental course, antecedents, correlates, and consequences of the two types of disorders. For both males and females, anxiety or depressive disorders during adolescence confer a strong risk for recurrences in early adulthood (Pine, Cohen, Gurley, Brook, & Ma, 1998).

Several epidemiological studies also indicate that anxiety disorders are more common in girls than in boys and these differences become more pronounced during adolescence and continue through adulthood (e.g., Anderson et al., 1987; Kashani & Orvaschel, 1990; Kessler et al., 1993; Lewinsohn, Gotlib, et al., 1998; McGee, Feehan, Williams, & Anderson, 1992). The description that follows draws from a comprehensive review of sex differences in different types of anxiety disorders in children and adolescents by Albano and Krain (2005). In general, girls with anxiety disorders tend to experience somatic complaints at a higher rate than boys. Female adolescents present with more compulsions, more symptoms overall, and greater impairment than male adolescents with Obsessive-Compulsive Disorder (Berg et al., 1989; Maggini et al., 2001; Valleni-Basile et al., 1994). Panic Disorder is more common among female than male adolescents (Kearney & Allan, 1995), and this sex difference continues into adulthood. Panic attacks in females are associated with advanced pubertal development (Hayward, Killen, Hammer, & Litt, 1992; Morris & March, 2004). There are also sex differences in the presentation of social anxiety symptoms (Weinstock, 1999). Studies of children with phobic disorders consistently find a higher prevalence among females in community and clinical samples (Ollendick, King, & Frary, 1989; Strauss & Last, 1993). Adolescent girls and women are at higher risk for the development of PTSD than are boys and men (Breslau, Davis, Andreski, & Peterson, 1991; Hanna & Grant, 1997; Kessler et al., 1994), but apparently only when PTSD is comorbid with other disorders, such as depression (Kilpatrick et al., 2003). Subclinical social anxiety is common in children and adolescents, especially for girls. Girls report higher levels of social anxiety than boys, particularly the social evaluative aspect (Crick & Ladd, 1993; LaGreca & Stone, 1993; Vernberg, Abwender, Ewell, & Beery, 1992).

Genetic/Biological Explanations

There is substantial evidence for familial transmission of anxiety disorders. Although the extent of genetic versus environmental influences is still debated (see Feigon, Waldman, Levy, & Hay, 2001; Rose & Ditto, 1983; Silove, Manicavasagar, O'Connell, & Morris-Yates, 1995; Wood, McLeod, Sigman, Hwang, & Chu, 2003), heritable factors

play a role (Crowe, Noyes, & Persico, 1987; Kendler, Heath, Martin, & Eaves, 1986; Noyes, Clarkson, Crowe, Yates, & McChesney, 1987). In behavior genetics research on anxiety at 7 years of age, both physiological and social anxiety symptoms showed heritability (Warren, Schmitz, & Emde, 1999). Lichtenstein and Annas (2000) have reported sex differences in heritability of types of irrational fears in 8- to 9-year-old twins. Similarly, Kendler, Jacobson, Myers, and Prescott (2002) found sex-specific genetic risk factors for agoraphobia, social, situational, and blood-injury phobias. The authors note the limited power of twin studies, even with large sample sizes, to resolve sex-specific genetic effects.

Disinhibited behavior patterns reflect daring and fearlessness, which are more common in boys than girls. Effortful control, which requires restraint and the ability to inhibit oneself, is more characteristic of girls than boys (Else-Quest et al., in press). Inhibited temperament in young children is associated with the later development of anxiety and anxiety disorders. Sex differences in behavioral inhibition are not always apparent early in life, but developmental trajectories appear to differ (Kagan, 2001). Behavioral inhibition (high reactivity in infancy and fearfulness at 2 years) predicted anxiety at 7.5 years of age more strongly in girls than boys. For girls, but not boys, early behavioral inhibition predicted later sympathetic activation of the cardiovascular system when confronted with an aversive stimulus (white noise).

Neurobiological mechanisms are implicated in the development of anxiety disorders, but there is little research on possible sex differences. This is puzzling given the sex differences seen early on in life, with girls more anxious and fearful than boys, and the physiological symptoms that often accompany anxiety (shortness of breath, palpitations or racing heart, shakiness, dizziness, flushes/chills, sweating, and headaches). This physiological reactivity is manifested both in central nervous system and autonomic nervous system activity. The fact that males more often show patterns of low autonomic arousal than females suggests the need to consider these factors in relation to (sex differences in) anxiety, as well as to examine differences in brain structure, function, and activity that may play mediating and moderating roles.

The startle reflex is a psychophysiological measure of reactivity that may be a vulnerability marker for anxiety. An early predisposition to react fearfully may reflect enhanced susceptibility. Behavioral inhibition has been linked both to anxiety disorders and risk for anxiety disorders by having a parent with an anxiety disorder (see Grillon, Dierker, & Merikangas, 1998). Grillon et al. found that

startle not only discriminated between children at low and high risk, but did so in different ways for high-risk males and females. For high-risk females, overall startle levels were elevated compared to other groups, suggesting generalization of fear to the entire experimental context. In contrast, high-risk males showed greater magnitude of startle potentiation during aversive anticipation, a more context-specific response. Sex differences in the brain structures of these high-risk groups may underlie affective responses to explicit (i.e., threat signal) and contextual (i.e., experiment room) threatening stimuli. The amygdala is implicated in startle response to explicit and contextual cues, whereas the bed nucleus of the stria terminalis is involved in response to contextual cues (M. Davis, Campeau, Kim, & Falls, 1995).

Another promising approach for understanding neural structures implicated in anxiety involves the use of fMRI. McClure et al. (2004) compared adolescent and adult males' and females' responses to threat. Adult women activated orbitofrontal cortex and amygdala selectively to unambiguous threat cues, and adult men and adolescents of both sexes showed a less discriminating pattern of activation. Sex differences in neural responses to threat may not be fully apparent until adulthood; a more definitive answer awaits further research with larger sample sizes and at different stages of development. This work is consistent with other studies showing heightened reactivity to threat by females, for example, greater accuracy in identifying anger and hostility, increases in skin conductance, and startle potentiation to threatening scenes.

There is also some evidence that males and females differentially engage brain structures associated with processing of emotional stimuli (orbitofrontal cortex, amygdala, and anterior cingulate gyrus; see McClure et al., 2004). Various hormonal changes affecting neurotransmitter and other systems that interact with hormones released in response to stress also may modulate anxiety in females (Goodyer, Herbert, Tamplin, & Altham, 2000; Rubinow & Schmidt, 1996; Slap, Khalid, Paikoff, Brooks-Gunn, & Warren, 1994; Suman, Nottelmann, & Inoff-Germain, 1987). Early puberty is associated with greater anxiety in females only. The mechanisms accounting for associations between pubertal timing, hormonal activity, and anxiety are not yet understood (Hayward & Sanborn, 2002).

Environmental Explanations

Initially, the parent-child relationship provides a primary interpersonal context where boys and girls can learn to become fearful (Gerull & Rapee, 2002). As children mature,

they are exposed to a wider range of behavioral models and contexts that include teachers and peers. Thus, there are further occasions to observe models that vary in how children cope with challenging and novel situations, as well as in the anxiety and fear they show. Socialization research intended to explain normative sex differences may also be relevant to more extreme variations. Boys are allowed and encouraged to explore their physical environments, which creates opportunities to master the unfamiliar and to feel comfortable or safe in a variety of contexts. In contrast, girls' exploration is often curtailed. Agoraphobic individuals are at ease only when they are close to home, finding it difficult or impossible to traverse certain distances.

A number of socialization experiences may contribute to heightened anxiety in girls. Fearfulness is accepted and sometimes encouraged in girls, but is less tolerated in boys. Parents are more tolerant, however, of anger, assertion, and misbehavior in boys. Society and culture reinforce these messages. One would expect that these processes would leave girls feeling more insecure, fearful, and anxious, whereas boys would be more likely to gain confidence and certainty in their actions. Research is needed to examine these different socialization processes in high-risk environments. This would help to determine when socialization processes are unrelated to psychopathology and when they help to shape sex differences in internalizing problems.

In addition to the family environment (Ginsburg, Siqueland, Masia-Warner, & Hedtke, 2004), peer relationships may play a critical role in shaping sex differences in pathological anxiety states (LaGreca & Lopez, 1998). Peer victimization has a greater effect on anxiety levels of girls than boys (Crick & Bigbee, 1998; Grills & Ollendick, 2002). Girls not only report more anxiety than boys, but being victimized leads to more negative opinions of themselves, which, in turn, makes them vulnerable to increased anxiety. Boys may more often externalize victimization experiences and view their peers rather than themselves in negative terms. Blaming others may protect against the development of anxiety but create risk for externalizing problems.

Several factors more common to girls than boys are associated with risk for anxiety as well as depression; these include more major life events, higher self-consciousness, lower self-esteem, and more emotional reliance (Lewinsohn, Gotlib, et al., 1998). Girls also report higher social competence and more social support from friends, which can be viewed as a trade-off that confers advantage in social relationships but that has an emotional cost (Rudolph & Conley, 2005). That is, interpersonal sensitivity is linked with social skills but also with emotional distress. This

may be reflected at the physiological level as well. Recently, Shirtcliff, Booth, and Granger (2004) showed that several aspects of social competence were associated with trait cortisol across a 2-year period in girls only. There was an interaction with social anxiety, specifically fear of negative evaluation, such that socially competent girls who were also fearful had high trait cortisol. Also consistent with the depression literature, sex differences in anxiety in adolescence result from differences in interpersonal stress and emotional reactions to stress (see Rudolph, 2002, for a review) and perceptions of negative interpersonal events as stressful (Wagner & Compas, 1990). Because females place greater value on close relationships than do males, they are also more affected by separation and loss, becoming anxious and depressed (Goodyer & Altham, 1991). In prospective epidemiological research, prediction of Generalized Anxiety Disorder in adults from stressful life events in adolescence was seen only for females, suggesting enduring negative effects (Pine, Cohen, Johnson, & Brook, 2002).

One common explanation for sex differences in anxiety (as in depression) is that of sex-role orientation. Feminine sex role in adults (both males and females) is related to increased self-report of fears, whereas masculine sex role is related to less fear (Carey, Dusek, & Spector, 1988; Dillon, Wolf, & Katz, 1985; Ginsburg & Silverman, 2000; Tucker & Bond, 1997). Essex and colleagues (2005) have identified two pathways to later internalizing problems. One pathway began with children who were temperamentally inhibited and prone to sadness as preschoolers, and socially inhibited in the face of new social and academic challenges as they transitioned into school. The other pathway was defined by girls who expressed more prosocial behaviors as they made the school transition. Anxiety and depression in third grade thus may be partly the product of biological sex and socially constrained roles. The connections between prosociality and anxiety/depression speak to possible adverse consequences of a strong interpersonal orientation as childhood precursors to later internalizing problems. In another study, prosocial themes in 7-year-olds' representations of conflict and distress (more common in girls than boys) predicted greater anxiety in girls but not boys in early adolescence (Zahn-Waxler et al., 2005).

Links between Anxiety and Depression: A Developmental Perspective

Most of the work reviewed to this point has focused on explanations for sex differences in depression and anxiety that appear in adolescence (see Zahn-Waxler, 2000), with

limited attention to childhood precursors. We know that externalizing problems emerge early in life, are more common in boys than girls, and show substantial continuity across time. Not only are girls much less likely than boys to engage in disruptive, antisocial, physically aggressive behavior during childhood, but when they do aggress they are more likely also to be depressed and anxious. This "gender paradox of comorbidities" (Loeber & Keenan, 1994) suggests that even "poorly behaved" girls experience greater internal pressures, constraints, and distress than boys with similar problems. Comorbidity of anxiety and depression is more common in girls than boys, whether or not externalizing problems also are present. Exploration of early and middle childhood may provide insights about why internalizing problems more often emerge later in development than externalizing problems. Comorbidity patterns in childhood may provide clues not only about sex differences in depression, but also why girls vary among themselves.

Childhood Antecedents of Depression

A decade has passed since the seminal paper by Nolen-Hoeksema and Girgus (1994) on different models for explaining sex differences in depression that appear to first emerge in adolescence. Since that time evidence has continued to accrue for model 3, the developmental model. It posits that vulnerability factors more common to girls than boys may be present in childhood, but lead to depression only in the face of challenges that increase in adolescence. Several of the risk factors for girls and protective factors for boys appear to reflect either extreme expressions of normative sex differences in early child characteristics and socialization experiences or normative differences that occur in the context of particularly challenging environments. A body of literature on childhood antecedents of adolescent and adult depression has begun to emerge (Block & Gjerde, 1990; Block et al., 1991; Gurian, 1987; Keenan & Hipwell, 2005; McCauley et al., 2001; Nolen-Hoeksema & Girgus, 1994; Zahn-Waxler, 2000; Zahn-Waxler et al., 1991). In our analysis, we emphasize early anxiety as a precursor to later depression. Anxiety shows stability over time in childhood (e.g., Ialongo, Edelsohn, Werthamer-Larsson, Crockett, & Kellam, 1995). The female preponderance in Major Depression may be secondary to a sex difference in specific anxiety disorders. The fact that Generalized Anxiety Disorder and Panic Disorder often precede depressive episodes in early adolescence suggests that early anxiety may lead to later depression, especially in girls (Parker & Hadzi-Pavlovic, 2004; also see Hankin & Abramson, 2001).

Several longitudinal studies now suggest that anxiety is often an integral feature of depression and that it precedes depression developmentally, and hence may be a prodromal sign of depression. Anxiety disorders in childhood and adolescence often precede and predict later depressive disorders. In one retrospective study of children with comorbid anxiety and depression, two-thirds became anxious before they became depressed (Kovacs, Gatsonis, Paulauskas, & Richards, 1989). Several prospective longitudinal studies have found that anxiety temporally precedes depression in children, adolescents, and even young adults (e.g., Breslau, Schultz, & Peterson, 1995; D. A. Cole, Peeke, Martin, Truglio, & Seroczynski, 1998; Lewinsohn, Gotlib, & Seeley, 1995). Prepubertal-onset anxiety disorder precedes recurrent Major Depression across generations in high-risk families (Warner, Weissman, Mufson, & Wickramaratne, 1999). In one study, inhibited 3-year-olds were unassertive and depressed at 21 years (Caspi, 2000). In another study, inhibited temperament in toddlers predicted generalized social anxiety in adolescence for girls only (C. E. Schwartz, Snidman, & Kagan, 1999).

Rumination in childhood can help to explain developmental associations between early anxiety and later depression. Although research has focused on ruminative responses *to* depression beginning in adolescence, rumination is likely to be present *before* depression develops. Rumination involves worry, perseveration, and even obsession (at times) about one's inner state and may begin in childhood as anxiety and worry develop. Rumination can magnify problems, overwhelm the child, and eventually create depression. It may also maintain or exacerbate depression by augmenting accessibility and recall of negative events (Bower, 1981).

A Biosocial Analysis of Childhood Precursors of Adolescent Depression

Because anxiety involves biological dysregulation of limbic, vegetative, and autonomic systems, the heightened, sustained arousal can eventually tax these systems, causing the organism to withdraw from environmental stimulation and shut down—in short, to become depressed. Not all depression is preceded by anxiety, and anxiety does not always lead to depression. But the pathway from anxiety to depression occurs with sufficient regularity to postulate that anxiety often plays an etiologic role. Because females are more likely than males to develop depression and to have earlier (and also comorbid) anxiety, girls would be expected to experience a developmental pathway from anxiety to depression more often than boys.

The abrupt appearance of depressive symptoms in adolescents and adults, without clear external triggers, is sometimes taken as evidence both for discontinuity of depression in development and for the primacy of biological processes. However, this depression may result from earlier stress and trauma. Post and colleagues (Meyersburg & Post, 1979; Post et al., 1996) proposed a crucial role for stressful or traumatic life events in precipitating initial depressive episodes in genetically predisposed persons. Initial episodes lead to future episodes that over time occur in closer proximity and eventually without environmental precipitants. This model was derived from work on the “kindling” of seizure disorders, in which seizures become more spontaneously generated over the years. Based on this work, F. K. Goodwin and Jamison (1990) argued that depression appearing “out of the blue” in young adults may have origins in early environmental trauma that helps create biological vulnerability. Repeated exposure to psychological stress over time may sensitize children so that later on, even brief exposures to similar stressors (or even thoughts and images in the absence of apparent stress that serve as reminders) could induce depression.

Dienstbier (1984) has proposed that different temperaments might lead to different emotion-attributional styles and levels of guilt. Proneness to emotional tension should result in intense discomfort and distress following transgression or stressful events. When distress is internal, the child is more likely to experience the links between tension and transgression and come to experience anticipatory anxiety. Temperamentally anxious children may develop “affective maps” or “somatic markers” of their experiences where threat- or stress-related information becomes particularly salient (Damasio, Tranel, & Damasio, 1991; Derryberry & Reed, 1994). This physiological reactivity may facilitate the early, rapid development of mechanisms related to conscience, such as guilt and restraint from wrongdoing, as well as feelings of responsibility in emotionally challenging encounters that do not involve transgression.

We propose that young girls not only are more likely than boys to experience anxiety, but also to interpret their environments in ways that create depressive cognitions. Because of their strong interpersonal orientation, girls are often in close physical proximity to caregivers. This can influence how the family climate is represented in conscious and unconscious memory, the scripts girls develop about early family life, and the accessibility of these memories. The literature on emotion language provides clues about how negative emotions and cognitions become fused as young girls are drawn into a communication process that is

depressogenic in nature (see review by Zahn-Waxler, 2000). Parents (mainly mothers) talk more about internalizing emotions (sadness, fear), providing greater detail and elaboration, with daughters than sons. Distressed and depressed parents talk more about these negative emotions than do well mothers (Zahn-Waxler, 2000). Young girls in these families will often be in a position to internalize emotional negative scripts that can be readily accessed.

Greater access to negative affect-based memories about family life or other social relationships (e.g., with teachers, friends, and classmates) that are unhappy and conflictual may provide material for a nascent form of ruminative coping and negative cognitions that may contribute to later depression. Because this process is likely to occur more often with young daughters than sons, girls may come to dwell more on negative events where they have little or no control. Through a complex set of processes socialization is thought to prime these memories and affective, physiological arousal (anxiety) to ingrain them into memory. There are many ways in which early negative emotions, behaviors, and cognitions could combine and lead to later depression, particularly for girls. We consider one prototypic model: the development of a depressogenic style in a young girl of a depressed parent who comes to feel guilty and responsible for the parent's problems. Other adverse environmental conditions could have a similar effect. Boys would not necessarily be immune to these processes, given similar temperaments and experiences.

During the preschool years, children can easily become overinvolved in parental conflict and distress. For example, they try to get fighting parents to make up or to help or cheer up a depressed mother (Cummings, Zahn-Waxler, & Radke-Yarrow, 1981; Radke-Yarrow, Zahn-Waxler, Richardson, Susman, & Martinez, 1994). They also develop *scripts* of overinvolvement in others' distress that include themes of empathy and guilt (Zahn-Waxler, Kochanska, Krupnick, & McKnew, 1990). These patterns are more common in girls than boys. Thus, girls of depressed mothers tend to become overinvolved in another's distress. They also show unassertive, submissive ways of coping with conflict (Hay, Zahn-Waxler, Cummings, & Iannotti, 1992), whereas boys do not.

These patterns of participation in parental conflict and distress, in conjunction with high levels of anxiety and internalized distress, create a possible pathway to depression. In attributional theories, adult depression is characterized by overwhelming feelings of both helplessness and responsibility. A young child with an emotionally distressed caregiver fundamentally cannot help the parent, and consequently this

may lead to feelings of helplessness and failure. The belief, however, that they can create change would be intermittently reinforced by their occasional successful efforts to assume responsibility. These children also become part of a large climate of despair by their close proximity to parental distress, with contagion of mood a likely outcome. Thus, young children, more often girls, could experience depression-like symptoms of helplessness and responsibility early and repeatedly due to empathic overinvolvement. These girls could come to feel that life requires more from them than they can give, leading to defeatism and despair. Although family stress negatively impacts the mental health of both girls and boys, having a strong caring orientation or involvement in family processes in the context of parental psychopathology and discord is seen as particularly harmful to girls (Gore et al., 1993).

In summary, the literature on young children suggests that most of the risk factors that create disproportionate risk for depression in adolescent girls are set in place much earlier and that childhood anxiety may provide a pathway to later depression.

Eating Disorders

Few psychiatric disorders are as clearly sex-linked as are Anorexia Nervosa (AN) and Bulimia Nervosa (BN; American Psychiatric Association, 2000). AN is marked by self-starvation; BN involves a syndrome of bingeing and purging. A review of epidemiological studies of AN suggests that it occurs in eight or more women for every one man, and the difference for BN may be larger (Pawluck & Gorey, 1998). The criteria for diagnosing these disorders are quite restrictive, and many females who experience substantial eating problems do not qualify for a clinical diagnosis. Studies that focus on less severe eating problems, such as weight and shape dissatisfaction or dieting, consistently involve many more females than males, beginning in elementary school. Although it appears in all American ethnic groups (Smolak & Levine, 2001), AN is found in lower rates in African American girls, which may be related to more flexible ideal body images. At least among girls, poor body image predicts the development of eating disorders (Attie & Brooks-Gunn, 1989; Stice & Bearman, 2001).

Several community-based studies have examined the prevalence of eating disorders (see Garvin & Striegel-Moore, 2001, for a review), but only one included men and examined only AN because BN had not yet been officially recognized. Relatively little research has been done on preadolescents, adolescents, ethnic minority groups, and

males (Garvin & Striegel-Moore, 2001). More epidemiological data are needed to make definitive statements about the prevalence of eating disorders. Current estimates are that AN occurs in less than 1% of postpubertal American women (Garvin & Striegel-Moore, 2001). BN is considerably more common, with a lifetime prevalence rate of 3% (Garvin & Striegel-Moore, 2001). Among adolescents, the rates are probably lower, with 0.5% to 1.0% meeting criteria for AN and 1% for BN (Thompson & Smolak, 2001). Many more females suffer from subthreshold disorders. The rate for subthreshold and full-syndrome eating disorders may be as high as 10% among adolescents (Agras, 2001).

The vast majority of research concerning eating disorders has been done with females. Hence, the diagnostic criteria have been developed based largely on females' symptoms and do not reflect a lack of sensitivity to them. However, some of the criteria may be arbitrary in ways that lead to underdetection of the problem in children (e.g., inclusion of amenorrhea as a diagnostic criterion for AN). Of the disorders that are comorbid with AN and BN, depression is most frequent. Depression and eating problems co-occur at subclinical levels starting before age 14 (Graber & Brooks-Gunn, 2001). Depression and eating problems may be causally related. For example, Stice and Bearman (2001) reported that negative body image and disturbed eating predict the development of depression in adolescence.

Girls are more likely than boys to report disturbed eating attitudes and behaviors (A. Field, Camargo, Taylor, Berkey, Robert, & Colditz, 2001). They more often think they are overweight when they are not and more often engage in binge eating. Girls' eating problems increase with age, whereas boys do not, and may be related to the increasing pressure with age for girls to be thin. Both boys and girls agree that weight plays a larger role in determining attractiveness for teenage girls than for boys (Jones, 2001). Puberty can also be seen as a time that takes girls away from their thin ideal body shape, whereas boys move closer to the male body ideal of greater size and muscularity.

Genetic/Biological Explanations

Some studies have shown fairly substantial rates of MZ twins' concordance for AN and BN (e.g., Bulik, Sullivan, Wade, & Kendler, 2000). Recent data suggest a genetic linkage signal for AN on chromosome 1 and for BN on chromosome 10p (Bulik et al., 2003; Devlin et al., 2002). Genetics are implicated in obesity, which is a risk factor for eating disorders (Meyer & Stunkard, 1993) and in this way may indirectly affect the development of eating disorders.

Information about biological factors is quite limited. Prospective studies that would include biological assays prior to the emergence of an eating disorder are not feasible given the low rates of occurrence and the high cost of the tests. Serotonin and dopamine levels have been implicated in the etiology of eating disorders (Kaye & Strober, 1999), and pharmacological studies provide some support as well. However, this literature is based on comparisons of neurotransmitter and hormonal levels of recovered anorexics and bulimics to normal females. It is not known how long it takes to recover; moreover, these disorders may permanently alter brain chemistry. In one prospective study, negative emotionality during the preschool years predicted a drive for thinness in adolescence (Martin et al., 2000).

Eating disorders are more common in girls who reach puberty early than those who are on time or late maturers. Girls gain as much as 40 pounds during puberty and begin to have a normative higher percentage of body fat compared to males. It is not surprising that girls become dissatisfied with their body, particularly when they mature early. What is less clear is why a relatively small proportion go on to engage in health- and life-threatening activities. It will be important to learn more about the interaction of biological and psychological forces. For example, Smolak, Levine, and Gralen (1993) reported that girls who went through puberty early and began dating early scored higher on a measure of disturbed eating later in adolescence, compared to girls who experienced *either* early puberty *or* early dating *or* neither stressor.

Environmental Explanations

Parents' comments have been shown to affect children's body esteem, beginning in elementary school (see review by Smolak, 2005). Daughters appear to be more affected than sons, even when parents do not respond differentially to them (D. Schwartz, Phares, Tantleff-Dunn, & Thompson, 1999; Smolak, Levine, & Schermer, 1999). Adolescents whose fathers were worried about the child's body shape were more likely to be constant dieters a year later (A. Field et al., 2001). Some (e.g., Smolak et al., 1999) but not all (e.g., Attie & Brooks-Gunn, 1989) researchers find that maternal modeling of body image and eating problems is related to daughters' eating problems.

Body objectification theory (Fredrickson & Roberts, 1997) is relevant to the heightened risk of females to develop eating disorders. Sex differences in body image are proposed to result from differences in how men and women's bodies are treated by society. Women's bodies are much more likely to be looked at, evaluated, and treated as

objects. Females learn that males' opinions about their appearance are important to their well-being. Already by third grade about 75% of girls have experienced sexual harassment (Murnen & Smolak, 2000). By middle school, this becomes normative for girls, and the threat of date rape begins (Bryant, 1993; J. Silverman, Raj, Mucci, & Hathaway, 2001). Also at this time, girls try to reduce such threats (e.g., by avoiding events or not speaking in class). At the same time girls are learning that their body poses a risk, they are also learning that being attractive may help them succeed socially and professionally.

Fredrickson and Roberts (1997) propose that girls gradually internalize that objectifying gaze and self-monitor their attractiveness, including whether they are thin enough. This leads to the normalization of body dissatisfaction among adolescent girls and women. Both experimental and longitudinal data indicate that one of the best predictors of eating problems is internalization of the thin ideal (Thompson & Stice, 2001). There are several reasons girls become susceptible to cultural pressures. These include stronger investment in social relationships, exposure to more consistent pressures from multiple socialization agents, and greater likelihood of living in a culture of thinness than boys (see review by Smolak, 2005). Girls are more likely than boys to be influenced by messages about body image from peers, parents, and media, yet there are signs that images of the ideal male body are becoming more unrealistic (Pope, Olivardia, Gruber, & Borowiecki, 1999). It will be important to learn whether boys increasingly experience these pressures and, in turn, their risk for eating disorders. Perfectionism is thought to play a role in the development and maintenance of eating disorders (Abramson, Bardone-Cone, Vohs, Joiner, & Heatherton, 2005; Shafran & Mansell, 2001). It would be important to study perfectionism in females and males, as well as emotions relevant to the pursuit of perfection and the failure to achieve it, namely, guilt and shame (Jambekar, Masheb, & Grilo, 2003).

PERSONALITY TRAITS, DISORDERS, AND PROBLEMS

This section briefly explores questions about the developmental antecedents of personality disorders and the role of personality in other disorders. Unlike other sections, there is little in the way of theory or data—only some important developmental questions that merit further consideration. Personality disorders involve an enduring, stable pattern of cognitions, emotions, and behavior that

are considered atypical for one's culture and that result in marked reductions in functioning for the individual (American Psychiatric Association, 2000). Traditionally, clinicians and other mental health professionals have viewed personality as lacking in cohesiveness and durability prior to the age of 18, which has contributed to a nondevelopmental emphasis and a lack of empirical data on the etiology and course of these disorders (Bleiberg, 2001; Geiger & Crick, 2001; Kernberg, Weiner, & Bardenstein, 2000; Paris, 2003). This is puzzling given the preponderance of literature on stability of temperament, which is viewed as an early expression of personality. Moreover, personality has been posited to begin forming early in life, substrates of which may be present at birth (Hartup & van Lieshout, 1995). Diagnosis of Antisocial Personality Disorder requires a developmental history of conduct problems; developmental precursors have not been posited for other personality disorders for the reasons noted. Research is needed on early variations in personality that may represent different vulnerabilities for males and females for the development of different personality disorders.

There are sex differences in the prevalence of a number of personality disorders (American Psychiatric Association, 2000). Some are more typical of men (e.g., Antisocial Personality Disorder, Narcissistic Personality Disorder) and others more typical of women (e.g., Borderline Personality Disorder, Histrionic Personality Disorder; American Psychiatric Association, 2000; J. D. Carter, Joyce, Mulder, Sullivan, & Luty, 1999; for a review, see Paris, 2003). Because boys are far more likely than girls to be diagnosed with CD they are also at later greater risk for Antisocial Personality Disorder. Results from one prospective community study have also shown impulsive disorders like CD and ODD are also precursors to Narcissistic Personality Disorder (Kasen et al., 2001). Parental maltreatment can be a precursor of Borderline Personality Disorder and other disorders as well (Paris, 2001). Notably, the sex differences in the types of personality disorders mirror extremes of normative differences seen even in childhood and adolescence, that is, extreme antisocial behavior and inflated self-esteem in males versus relationship problems, emotionality, and dependency in females.

Geiger and Crick (2001) have proposed a developmental psychopathology model of factors that indicate risk for personality pathology during childhood and adolescence. In this model, it is posited that childhood features associated with atypical personality development may be identified in terms of difficulties negotiating developmentally

appropriate, normative tasks that have relevance for particular disorders. Based on a content analysis of *DSM* criteria for diagnosis of personality disorders, features of pathology were identified as relevant to the nature of particular aspects of personality disorders, as well as to maladaptive development during childhood. An example is a childhood tendency to view the world in a hostile, paranoid manner (Crick & Dodge, 1994). Paranoid ideation may indicate a type of compromised social cognitive competence indicative of Borderline, Paranoid, or Schizotypal Personality Disorders.

The childhood tendency to view the world in a hostile, paranoid manner is elicited in different contexts for boys and girls that may influence the nature of their ideation and the later form of their personality problems. These and other features identified by Geiger and Crick (2001) may provide fruitful avenues for exploring differential pathways toward (and away from) different personality disorders for boys versus girls. Additional theoretical models, as well as empirical tests of these models, are needed before the role of development and sex in personality pathology development can be determined. Research on Axis II disorders utilizing longitudinal designs, targeting equal numbers of boys and girls, and using large community samples in addition to clinical samples would help to increase existing knowledge of personality pathology.

The personality trait of neuroticism has been implicated in depressive disorders and sex differences in depression. Although causal connections are difficult to establish, recent research has suggested that neuroticism is a better predictor of depression in adult females than males, with females scoring higher than males on both of these dimensions (R. D. Goodwin & Gotlib, 2004). Notably, women also scored higher than men on agreeableness, extraversion, and conscientiousness, and men scored higher on openness to experience, dimensions that also correspond to childhood sex differences discussed earlier, for example, compliance and responsibility in girls and exploration in boys. From a developmental perspective, early anxiety, inhibition, and fearfulness may be temperamental qualities that are forerunners of neuroticism, suggesting a causal rather than correlational role of neuroticism in depression.

Neuroticism typically is defined in terms of negative affectivity, which includes the combination of extrapunitive (e.g., anger, hostility) and intropunitive (e.g., sadness, fear/anxiety, guilt) negative emotions. In the adult literature, these have been shown to be viable constructs at both their combined and individual levels (Watson & Clark, 1992). Neuroticism technically includes anger/hostility as

well as the emotions more directly related to internalizing problems, but it is possible that anger/hostility plays a lesser role. It would be useful to examine the predictive power of neuroticism for depression, with and without the externalizing component. Unlike adults, where women score higher on neuroticism, young boys and girls do not differ on the temperament trait of negative affectivity (Else-Quest et al., in press), a concept similar to neuroticism. A breakdown of negative affectivity into extrapunitive and intropunitive emotions at different stages of development and an analysis of continuities over time for both males and females would help to clarify the nature of precursors of neuroticism.

FUTURE DIRECTIONS

This overview of research on the development of psychopathology makes it abundantly clear that there are sex differences in types, rates, antecedents, correlates, trajectories, comorbidities, and consequences of problems in females and males. Although there are important similarities, it is essential to appreciate the differences in order to advance scientific knowledge and to develop more effective treatments. Evidence continues to accrue indicating the need for developmental models that allow for different parameters for males and females when genetic and environmental factors implicated in psychopathology are studied (Jacobson & Rowe, 1999). The long history of ignoring the possibility of gender-specific or gender-relevant models for the sake of parsimonious causal explanations has led to a sometimes oversimplified and fragmented understanding of the etiology of sex differences in psychiatric and psychological problems. Parenthetically, we have treated sex as a dichotomous variable in this review, consistent with how research participants were classified in the studies reviewed. The study of homosexuals and transgendered individuals regarding the issues addressed will be important in future research.

Conceptual Considerations

The construct of inhibition has emerged in this review not only as a symptom, but also as both a risk and protective factor for different forms of psychopathology in females and males. Bjorklund and Kipp (1996) proposed that cognitive inhibition mechanisms evolved from the need to control social and emotional responses in small groups of hominids for the purposes of cooperation and group cohe-

sion. Moreover, the pressures to inhibit certain potentially inappropriate social and emotional responses were thought to be greater on female than male hominids, resulting in enhanced inhibition abilities for females in a range of contexts. The motivation for inhibition stemmed from females' roles in bearing and rearing children and the need for greater parental investment than males, roles that continue to this day. Bjorklund and Kipp's reexamination of their own data and review of other research provided support for this point of view. Although sex differences may not be present for behavioral inhibition in children as a temperamental trait, there is substantial evidence that females are better able to inhibit and control their impulses, behaviors, and emotions than males, beginning early in life.

We have seen that inhibition also plays a role in several forms of internalizing psychopathology more common to females than males. Disinhibition, in contrast, is common to several forms of externalizing psychopathology and neurodevelopmental psychiatric problems seen more often in males. Inhibition had and still has adaptive value, but it carries risk for problems in functioning, particularly for females. That is, it may result in conscientious, responsible behavior under optimal conditions, and it may stifle normal development when other risk factors are present. The same is true of disinhibition, which is often problematic but under certain conditions creates openness to experience and opportunities for growth. It will be important to identify etiologic factors that distinguish adaptive and maladaptive functioning.

It will also be valuable to learn more about the development of the neural bases of inhibition, which are localized in functional areas of the neocortex, more specifically, the prefrontal cortex, which receives projections from the mediodorsal nucleus of the thalamus.

There are sex differences in maturation of the neocortex, with girls maturing faster (and thus able to inhibit a prepotent response earlier) than boys (A. Diamond, 1990). Most of the research on brain maturation has emphasized the deleterious consequences of delayed maturation for certain types of disorders more common to males. However, there may be risks associated with early maturation for other types of problems and disorders more common to females when coupled with other risk factors, some of which may not be obvious. For example, high intelligence is associated with depression, particularly in girls (Gjerde, 2005), who may better understand the implications of societal constraints. In conjunction with neural inhibitory processes, a pathway to anxiety and depression can be hypothesized. Early resilience may disguise problems such as

anxiety, and early vulnerabilities to depression may take a subtler, less recognizable form.

Delayed neural maturation due in part to high levels of circulating testosterone that hypermasculinize the brain early in development has been associated with the extreme male brain (Baron-Cohen, 2002). This is thought to increase the probability of certain kinds of problems associated with behavioral, motor, social, and emotional disinhibition, for example, sexual attacks and compulsions, physical violence and brutality, tics, and problems in social communication and understanding emotions. The extreme male brain theory has the advantage of grouping apparently disparate psychiatric and psychological problems in a single unifying framework. What it does not do, however, is explain why a given hypermasculinized individual is more likely to develop one type of problem (e.g., Autism) than another (e.g., Conduct Disorder). The theory is based mainly on observable differences that have yet to be examined in relation to genetic, neural, and hormonal patterns for both males and females and for different kinds of problems.

Another issue to be addressed is whether or not there is an extreme female brain, and if so, what are the distinguishing characteristics. Baron-Cohen (2002) suggests that there is, but that it is not relevant to psychopathology. The prototypic person would be highly empathic but deficient in object-related skills (e.g., classification, systemization, and spatial skills). Such a person would be good at organizing and making sense of the social world. In this view, because one can function in society even without scientific skills, such individuals would not be at risk.

What the extreme brain theory fails to consider, however, are the adverse consequences of a hyperdeveloped capacity for empathy (more common to females) similar to the adverse consequences of a hyperdeveloped capacity for systematizing (more common to males). Whereas the extreme of systematizing is viewed as maladaptive in Baron-Cohen's system, the extreme of empathizing is not, for the reasons just noted. Empathizing is defined broadly by Baron-Cohen (2002) to include the capacity to (1) share and take turns; (2) refrain from rough-and-tumble play, physical aggression, and violence; (3) show concern for another's distress; (4) infer others' thoughts and intentions; (5) decode facial and vocal expressions; (6) value interpersonal relationships; (7) engage in indirect or relational aggression, which requires better mind-reading skills than physical aggression; (8) use speech that is cooperative, reciprocal, and collaborative; (9) talk about emotions; (10) engage in sensitive parenting practices; and (11) prefer face and eye contact. Our literature review has revealed

links between some of these qualities (more common to females) and internalizing problems (also more common to females). A necessary expansion of the theory would include the extreme female brain as a risk factor for internalizing or inhibitory disorders, in contrast to externalizing and other forms of disinhibitory disorders and problems.

Earlier we discussed how sex-role stereotypes or exaggerations of feminine and masculine qualities are reflected in the different types of problems that males and females tend to develop. Baron-Cohen's addition of the systematizing dimension (at the extreme) provides an example of a framework for understanding types of male-dominated disorders like Autism and Asperger's syndrome, where there is often an intense interest in the world of objects, often to the exclusion of people. High-functioning individuals with these developmental disorders are sometimes highly gifted in areas like mathematics and physics. The origins of the idea of the extreme male brain derive from the conceptual work of Geschwind and Galaburda (1985), who discussed the role of an asymmetrical nervous system that included anomalous cerebral dominance and emphasized the role of testosterone in the intrauterine environment. They viewed these conditions as responsible not only for a range of developmental disorders but also for special talents more common to males than females. It is important to raise questions about such theories and to make certain that they are not used to justify stereotypes and prejudices about sex differences. At the same time, it is important to recognize that there may be some underlying biological bases for both assets and liabilities that are more common to one sex than the other.

Because the extreme male brain is broadly defined, including both the ability to systematize and lack of empathy and covering a wide range of disorders, one would anticipate different biological and environmental factors would be implicated. One important next step in research will be to determine whether there are different patterns of brain structure, function, and circuitry (and other biological and environmental processes) that underlie the different types of problems characterized by the extreme male brain and the extreme female brain. This framework could provide a starting point for examining how similar qualities of individuals can be adaptive or maladaptive, convey protection or risk, reflect resilience or vulnerability, and signal the fact that there are trade-offs or costs and benefits to be weighed.

Most of the relevant brain imaging work has been conducted with animals and adults. Few studies have compared females and males with a sufficient sample size, and even fewer are based on a developmental perspective. Some

EEG studies demonstrate different patterns of asymmetry for males and females at risk for depression (Miller et al., 2002; Tomarken, Dichter, Garber, & Simien, 2004). It would be fruitful now to follow-up such research on sex differences in brain imaging studies. Research with children and adolescents is needed to examine the evolution of possible sex differences in brain structure, function, and circuitry over time and how they interact with experience, symptomatology, and self-evaluation. One challenge will be to develop rigorous and realistic stimulus conditions for developmental paradigms.

R. J. Nelson (2004) has emphasized the importance of diminished self-esteem in the development of internalizing problems and how these may stem from interactions between brain structures devoted to social-cognitive appraisals and those involved in regulating affective responding. Based on neuroimaging research (e.g., Fossati et al., 2003) on the substrates that underlie self-referential thinking, that is, a network of activations in the medial and dorsolateral prefrontal cortex that relate to thinking about oneself, Nelson proposes ways that this self-reflective region may be co-activated with regions that organize affective responding in anxious individuals. The combined network of such neural activity may ultimately result in enduring low self-evaluation. Heller (1993) similarly has proposed that the higher rate of depression in females may be affected by certain coping strategies such as rumination that produce certain cognitions to influence the neurophysiological mechanisms underlying mood, in part, by activating certain regions of the brain. Because adolescence is likely to be a sensitive period for neurobiological organization relevant to self-concept (E. E. Nelson, Leibenluft, McClure, & Pine, in press), this is an ideal time to examine neural mechanisms underlying the ruminative and depressogenic cognitions, more common to girls, that are linked to anxiety and depression.

The Role of Emotions in the Development of Psychopathology

Relatively little research has been devoted to the issue of the role of emotions in the development of psychopathology. Emotions and psychopathology are sometimes viewed as redundant constructs, but this is far from true. Sometimes emotions are linked in obvious ways to psychiatric diagnosis or psychological classification; at other times they are not. For example, mood disorders may or may not involve the expression of sadness. Depression may involve an excess of other negative emotions (e.g., guilt, anxiety, anger, irritability); it may involve a lack of positive affect

(anhedonia) or a surfeit of positive affect in depressed individuals as they try to please others and mask negative feelings. Given the sex differences in many of these emotions, the study of the evolution of these emotions in their pathological forms and their associations with different kinds of problems will be important for understanding their etiologic significance. The picture becomes even more complex when one considers that (1) there are undoubtedly different subtypes of depression linked to different emotional patterns and ways these subtypes are expressed; (2) similar issues exist with respect to most other kinds of emotional and behavioral problems; and (3) co-occurring emotions will differ in relation to different patterns of comorbidity of psychiatric disorders and psychological problems. In addition to types of emotions, there is the question of the modulation, dysregulation, intensity, and suppression of emotions and how dysfunctional patterns may develop into different forms and manifestations of psychopathology in girls and boys.

Whereas many disorders and problems of childhood and adolescence are no longer present in adulthood, the opposite is not true. It is now widely believed that many or most adult problems originate earlier in life. This is why a developmental perspective is so important in trying to examine prospectively the early processes that come into play to influence later psychopathology (i.e., equifinality). The role of early emotions in the development of psychopathology is underexplored. One approach from a discrete emotions perspective would be to study processes by which particular emotions or combinations of emotions that underlie particular forms of problems become stylized, entrenched, possibly automatic ways of responding over time (Malatesta & Wilson, 1988). What factors contribute to the types of emotions seen more often in girls or boys, and what determines when they reflect too much of a good thing (bearing in mind that all emotions serve adaptive functions)? Another approach is to examine undifferentiated negative affectivity early in development to determine, for example, why the same constellation of negative emotions differentially predicts externalizing problems for boys and internalizing problems for girls (Rothbart, Ahadi, & Hershey, 1994). It may be that total undifferentiated negative affectivity scores are similar, but that boys show a preponderance of anger and hostility and girls show relatively more sadness, anxiety, and guilt.

Emotion dysregulation is a risk factor for child psychopathology beginning early in development (see Keenan, 2000). Given the increasing evidence for the early emergence of some forms of psychopathology, as well as precursor patterns, this would be a valuable future research

direction for understanding the etiology of sex differences in psychopathology. We have not discussed the diagnosis of psychiatric disorders in the 1st years of life because this work is more recent in origin and has not yet focused on sex differences (DelCarmen-Wiggins & Carter, 2004). It is to be hoped that this will change as more research is conducted.

Examination of emotions in boys and girls from high- and low-risk environments, in conjunction with assessment of socialization of emotions, is another important next step in this research area. Progress has been made in the development of instruments and observational paradigms to assess socialization of emotion (Chaplin et al., 2005; Eisenberg, Cumberland, & Spinrad, 1998; Klimes-Dougan et al., 2005; O'Neal & Malatesta-Magai, 2001) in ways that capture subtle but potentially powerful processes that help to shape the types of emotions that are acceptable or unacceptable for boys or girls to express. Although most of this research has focused on childhood, recent work indicates its relevance to understanding sex differences in psychopathology in adolescence and for exploring risk by gender interactions (Klimes-Dougan et al., 2005).

Methodological and Analytic Considerations

Many of the normative sex differences reviewed also were prominently present in the sections on psychopathology. Some have argued that if similar differences in problems are seen at both normal and clinical levels, this has no particular bearing on the etiology of sex differences in psychopathology. That is, the sex differences observed at clinical levels are just a reflection of base rate differences; to be etiologically informative, interactions must be demonstrated whereby the differences become exaggerated at clinical levels. Clearly, interactions provide essential information, but even in their absence much can be learned. For example, if girls show 2 to 3 times as many depressive symptoms as boys (or boys show 2 to 3 times as many conduct symptoms) within the normal range, these same ratios at the clinical level reflect a qualitative as well as a quantitative difference as suffering and dysfunction become evident.

Sex differences in base rates of symptoms also have implications for how symptoms are treated in different classification systems. In psychiatric systems, the number of symptoms required to be diagnosed with a disorder is absolute, so that males and females are treated equally in this regard. As we noted earlier, Zoccolillo (1993) recommended that fewer symptoms be required to reach criteria for conduct problems for females than males, given their lower base rates for certain forms of antisocial behavior, such as physical violence. A number of arguments have

been made against doing so. In several psychological systems, cutoffs are different for males and females, depending on the base rates of these problems in females and males in the general population. Thus, for example, use of standardized scores from such instruments as the Achenbach Child Behavior Checklist or the Revised Social Anxiety Scale for Children to identify risk groups for study will result in risk groups in which males have higher levels of externalizing problems and lower levels of internalizing problems than females at the onset. These differences in different classification systems raise the question of what it means to equate males and females on problems and how the data should be treated for research purposes.

This is part of a larger issue of what it means to control for sex in statistical analysis, where creating equal conditions through statistical control can end up playing a large role in determining the nature of the generalizations from our data sets. When studying sex differences in psychopathology, it is important to distinguish between methodological and statistical assumptions of equality. Our studies should be designed to compare and, when appropriate, equate males and females. This involves designing studies that (1) include both males and females, (2) include enough males and females to have the statistical power to detect/reject an interaction with gender, and (3) use observational scoring systems that are not gender-specific and that query behaviors seen in both sexes (e.g., physical, verbal, and relational aggression).

Statistically, our analytical strategies should discover the level of analysis at which sex differences emerge. Four distinct levels of sex differences are possible. First, boys and girls could differ in the measurement validity of a construct. For example, the measurement of salivary testosterone is more valid in boys than girls (Shirtcliff, Granger, & Likos, 2002). Second, boys and girls could have different latent factor structures so that constructs are weighted toward different items across the sexes. For example, attention problems may load with externalizing behavior problems in boys, but not girls (Granger et al., 2003). Third, sex differences in levels or prevalence of psychopathology or a risk/protective factor for psychopathology may be evident (Rutter et al., 2003). Fourth, risk and protective pathways for emerging symptoms may differ for girls and boys. This highlights the need for studies to be conceptually, methodologically, and statistically designed to examine sex differences *a priori*, not just dealt with as *post hoc* irritants.

The primary focus on one sex or the other in many past investigations has had adverse consequences for under-

standing the role of gender in the development of psychopathology. It will be more difficult in some areas than others to rectify these imbalances, particularly where disparities in prevalence rates are so large, for example, Autism and eating disorders. However, for both externalizing and internalizing problems, the disparities are often not so pronounced. The problem is perhaps more serious for research on externalizing problems, where in many studies girls were excluded from samples altogether. When girls have been included they have constituted a minority of the target groups of interest (e.g., children with ADHD; physically aggressive children), and the results obtained have been relevant primarily for boys. Although the same is sometimes true for internalizing problems, it has been an issue less often because greater efforts have been made to include as many boys in the samples as girls. In efforts to rectify problems of the past, sometimes only girls with externalizing problems are studied. This is at once laudatory and problematic because historical, contextual changes may have occurred in the interim and because only indirect comparisons of male and female samples can be made.

Research by Angold and colleagues (1996) provide an interesting example of the importance of including both males and females in the same research designs. They reported a phenomenon they called “disappearing depression,” wherein an all-male sample showed a fall in depressive symptoms between 8 and 11 years of age. This led to the proposal that, in contrast to girls, early puberty for males might be protective, and that differing psychological and social stressors for girls and boys also could play a role. However, in a subsequent study, they found the same fall in symptoms from 8 to 11 years in girls, illustrating both the difficulties posed by making inferences based on one sex and the value of follow-up research with the other sex. In another example, Tomarken and Davidson (1994) found that defensiveness was characterized by relative left frontal brain activation in an all-female sample. In a subsequent study (Kline, Allen, & Schwartz, 1998), this pattern was replicated for females, but males showed an opposite pattern.

In many studies, sex main effects have been considered to the exclusion of the interactions of sex with other salient factors. Although sex differences are interesting and important in their own right, a developmental psychopathology approach also requires exploration of the moderating role of sex. When interactions are considered, that is, to assess whether a given etiologic factor predicts problems exclusively or more strongly for one sex, traditional statistical procedures (e.g., ANOVA, hierarchical linear regres-

sion) pose limitations, as main effects are evaluated prior to interaction effects. This and other factors restrict the statistical power for testing interactions hypothesized to be significant for understanding the role of gender in the development of psychopathology. Frequently, this will lead to the appearance of null results that researchers accept as de facto proof of sex similarities and consequently collapse across the sexes in subsequent analyses. This may mask possible small but important effects. Also, although statistical techniques do provide ways to examine nonlinear relations, the majority of hypotheses and models tested are based on assumptions of linearity. Many of the gender-related factors and processes relevant to adaptation and maladaptation have been seen to operate differently depending on level and context; for example, physical aggression may be essential under some circumstances, and empathy has been described as at the center of what it means to be fully human. Both, however, have been linked to different forms of psychopathology when expressed in the extreme, and associations may be nonlinear as a particular attribute becomes increasingly maladaptive.

Analytic problems can contribute to deterministic understanding of biological predispositions, a simplistic understanding of psychosocial forces, and an ignorance of the complex and reciprocal relationship between biological and psychosocial forces. Interactive effects with other complex biopsychosocial moderators are overlooked (e.g., time, timing, context, and critical developmental windows), which does little to clarify the interactional nature of the etiology of sex differences in psychopathology. Researchers need to consider the level at which sex differences are expected and to entertain the possibility, even when sex differences are null, that similarities between the sexes should not be confused with equality between the sexes. Although equifinality may render males and females similar at one developmental stage, they can diverge along different developmental trajectories of risk and resilience (i.e., multifinality).

New approaches are needed to more adequately account for and statistically evaluate those effects that are most salient for advancing knowledge of the moderating role of sex in the development of psychopathology. Ascertainment of the relative strength of sex differences in associations between factors relevant to adjustment difficulties for boys versus girls is central to future research and theory development. Several statistical experts (e.g., Jessor, Van Den Bos, Vanderryn, Costa, & Turbin, 1995; McCall, 1991; McClelland & Judd, 1993) have emphasized the difficulties inherent in detecting moderators in field research and that

even interactions that are weak or modest in magnitude are noteworthy. Because existing statistical approaches are not effective for identifying moderator effects, which are important in research on gender, new approaches are needed. That interactions have emerged in the literature on both biological and psychosocial processes, despite these problems, attests to the importance of identifying different processes that may be present but undetectable through present conventional approaches.

It is recommended that data be presented separately for males and females even when interactions are not found, so that trends in individual studies may eventually be represented in meta-analytic reviews. This could be done for main effects as well. Hoffman (1977) provides a compelling example of a largely unnoticed effect until several samples were combined. In studies of newborns' reflexive cries in response to other newborns, girls were more responsive than boys. Reflexive crying is viewed as a primitive precursor of empathy, the quality described as deficient in the extreme male brain. It may reflect a hard-wired response that, consistent with Baron-Cohen's theory, differentiates male and female infants to a certain degree.

Prospective longitudinal approaches, which include equal samples of females and males, are needed to better clarify gender-related differences in etiologies and in trajectories. Growth curve modeling techniques may help to examine male and female trajectories over time as well as what factors track with changes in levels of symptoms. In examining correlates that track with level of symptoms among males and females, for any given disorder where prevalence rates differ, it will be important to test how well other correlates besides those commonly associated with the sex with greater prevalence rates track with problems for the other sex.

Research on gender and psychopathology will be advanced by recognition of the needs (1) for better and more diverse methods and paradigms, (2) for information at all levels of analysis (e.g., genetic, biological, psychosocial, environmental, societal) to better understand the etiology of emotional and behavioral problems of females and males, and (3) to resist premature conclusions about processes being similar *or* different for the two sexes, as both are likely to be true under certain circumstances. This is no longer an era of grand theories but one of necessarily more circumscribed theories that focus on particular structures, functions, and activity within different parts of the brain and body and different ways the organism engages with the external world and is influenced by it. The interactions of these internal and external worlds are sometimes

explored, but not frequently, and rarely from a developmental perspective. By starting with samples of males and females equated (as far as possible) on clinical problems and finding later sex differences (e.g., in prevalence, antecedents, comorbidities, and/or developmental trajectories), more stringent tests of (similar and different) mechanisms become possible.

Epidemiological studies with representative samples are important for establishing prevalence rates of problems (Rutter et al., 2003), yet we need also to understand how mechanisms may differ by gender, even in the absence of differences in sex ratio. Work with clinical samples is also needed, despite sample biases that sometimes may be present, for understanding of biases can lead to understanding of processes. Moreover, sample bias can be minimized in research that identifies separate groups of participants with normal, subclinical, or clinical levels of problems, who are not already receiving treatment, to be studied in the same research design. In this way it becomes possible to consider whether etiologic factors operate in similar or different ways, depending on the severity of problems. This is important because many of the generalizations about sex differences and interactions regarding either internalizing or externalizing problems are derived from psychological studies of subclinical levels of problems and have not directly assessed psychiatric symptoms.

Conclusions

Ultimately, the goals of research on gender and psychopathology are to minimize the problems and enhance the well-being of both boys and girls as they make developmental transitions to become independent *and* interdependent members of society. We have not addressed treatment because it is beyond the scope of this review. Because efficacy of interventions is rarely examined in relation to gender (Davies & Lindsay, 2004), relatively little is known about processes that contribute to possible differential effectiveness. We do know that pharmacological interventions may be more or less efficacious across the sexes, and side effects of drugs may interfere with treatment in females more than males (Yonkers & Brawnman-Mintzer, 2002). One can view psychotherapeutic treatments as socialization and learning experiences that allow the person to become more functional. There is some evidence that girls, particularly adolescent girls, are more responsive than boys to a range of psychotherapeutic treatments (Weisz, Weiss, Han, Granger, & Morton, 1995). Intervention research may provide clues about processes about dif-

ferential effectiveness and how treatments might be tailored as a function of gender.

It has been over 30 years since Maccoby and Jacklin (1974) published their seminal book on the psychology of sex differences. They concluded then that boys and girls were more similar than different, with one exception, that being a greater propensity for physical aggression and violence in boys. A multitude of studies have confirmed this difference since then, yet other notable and robust sex differences have been identified and there has been a dramatic expansion of interest and knowledge about these other differences. We have considered the implications of these other differences, as well as of physical aggression, for adaptive and maladaptive functioning of males and females. Thirty years from now there will be similar limitations to the generalizations drawn here, based as they are on information available at the time. Much of the research still focuses on sex differences per se, with less emphasis on within-sex variability. This leads to a focus on prototypic male and female patterns and how exaggerations (and/or combinations with certain risk factors) may reflect problems rather than normative differences. However, failure to conform to "sex-appropriate" behaviors by showing behaviors more common to the opposite sex also can have heightened adverse consequences, as we have seen, for example, for girls with Autism, ADHD, and conduct problems. Similarly, boys who show feminine interests and characteristics are at risk. Thus, the issues are far more complex, as future research will demonstrate. The most interesting questions have yet to be addressed.

Much of the work we considered was not explicitly formulated to examine biosocial interactions (Moffitt, Caspi, & Rutter, 2005), or even bio-bio or social-social interactions with respect to gender. Yet both the animal and human literature point to the fact that genetic and biological contributions to adaptation and psychopathology are often strongly dependent on environmental processes; moreover, environments alter biological structures and functions. As Wallen (1996, p. 364) puts it, "Nature needs nurture" in order to understand behavioral sex differences. Environmental and socialization processes are especially difficult to measure in large-scale prediction studies and hence may not fare well in making their roles known. Because mental health problems are often the result of a stress-diathesis process that includes both biological and environmental factors, equivalently valid and reliable assessment is necessary to understand the different directions of movement toward psychopathology of males and females. Moffitt et al. indicate that a major task

for future research will be to develop more adequate environmental measures to test crucial gene-environment interactions, especially given the advances in genotyping, brain imaging, and other biologically based measures. Continued pursuit of questions about the etiology of similarities and differences in males and females from a developmental psychopathology perspective can help to advance our understanding of their mental health problems and to alleviate their suffering.

ACKNOWLEDGMENTS

The authors wish to thank Jong-hyo Park, PhD, for her meticulous literature review for several sections of this chapter and her diligent editorial work. The senior author would also like to thank the National Institute of Mental Health Intramural Research Program for support in the preparation of this chapter.

SUMMARY	175
REFERENCES	175

In revising this chapter for the second edition of *Developmental Psychopathology*, we address numerous advances in knowledge and methods related to developmental issues in assessment, taxonomy, and diagnosis of psychopathology. The previous version of the chapter outlined applications of devel-

opmental perspectives to adult psychopathology as an important future direction. Since then, new research has addressed developmental issues in assessment, taxonomy, and diagnosis of adult psychopathology. Consequently, this chapter now takes account of psychopathology across the life span.

Another innovation is the inclusion of multicultural perspectives. Forced and voluntary migrations of millions of people to unfamiliar cultures raise many new challenges for mental health, educational, social, and correctional systems. At the same time, a growing body of research is revealing fascinating multicultural similarities and differences in psychopathology assessed by the same standardized procedures. This work provides a basis for applying what is now known about assessment, taxonomy, and diagnosis to culturally diverse groups. It also provides a foundation for the additional efforts that are needed. To set the stage for considering assessment, taxonomy, and diagnosis, we first outline the life span and multicultural perspectives that are now so important. Thereafter, we address the developmental and psychopathology components of developmental psychopathology, the nature of assessment, taxonomy, and diagnosis, relevant methodologies, life span and multicultural applications, the benefits of quantification, and future directions.

LIFE SPAN PERSPECTIVES

Developmental approaches to the study of psychopathology originated with efforts to advance our understanding of maladaptive functioning between birth and maturity (Achenbach, 1974, 1982; Cicchetti, 1984; Rutter & Garmezy, 1983). It is now clearly recognized that behavioral and emotional problems in the young need to be understood in relation to developmental sequences, norms, and processes. However, it is also becoming clear that developmental approaches are needed to understand psychopathology at older ages. In many countries, challenges posed by the growing legions of elderly people are raising awareness of the need to cope with developmental changes in functioning during the last decades of life. Developmental perspectives can also illuminate adaptive and maladaptive functioning in the early and middle adult years when many changes occur in social roles, relationships, responsibilities, careers, self-concepts, and biological characteristics, including health. Although developmental issues in assessment, taxonomy, and diagnosis have received more attention with respect to children and adolescents than adults, life span perspectives argue for expanding our horizons to include developmental issues pertaining to adults as well.

A particularly important issue concerns the need to obtain multisource data for purposes of assessment, taxonomy, and diagnosis. It is now widely accepted that no single source can serve as a gold standard for assessing

child and adolescent functioning. Instead, because agreement among informants is typically low to moderate (Achenbach, McConaughy, & Howell, 1987), assessment of children should include data from multiple informants. The data must then be systematically compared and integrated to identify both the consistencies and variations among reports of an individual's functioning.

In the assessment of elders whose mental competence may be questionable, it is common to obtain information from other informants, such as a spouse or grown child. In the assessment of younger adults, by contrast, data are typically obtained solely from the adults who are being assessed, mainly via interviews, tests, and questionnaires. Yet, meta-analyses of cross-informant correlations for assessment of adult psychopathology have revealed only modest agreement between self-reports and reports by others (Achenbach, Krukowski, Dumenci, & Ivanova, 2005). A major challenge for improving assessment, taxonomy, and diagnosis of adult psychopathology is therefore to apply to adults the principles and methods for integrating multi-informant data that have been developed for children and adolescents. Other lessons learned from the developmental study of child and adolescent psychopathology can also be applied throughout adulthood.

MULTICULTURAL PERSPECTIVES

Mental health professionals are increasingly expected to help people from diverse cultural backgrounds. In some cases, the need to cope with cultural diversity arises from influxes of foreign refugees and immigrants. In other cases, the need to cope with cultural diversity arises from migrations within a country. And in still other cases, the need to cope with cultural diversity arises from greater awareness of cultural differences among people who have long coexisted in a particular area.

Cultural diversity raises a variety of challenges for mental health professionals. Perhaps the most obvious is differences in language. Because mental health professionals may not be fluent in the languages of all the groups to be served, interpreters may be needed. Even when language is not a barrier, however, cultural differences related to ethnicity, religion, place of origin, and socioeconomic status (SES) may affect communications between mental health professionals and the people they serve.

For assessment, taxonomy, and diagnosis of psychopathology, a fundamental multicultural issue is whether the same procedures can be used to assess people from different cultures. This issue raises questions such as the following:

- Can mental health professionals readily use the same procedures to assess the problems and adaptive functioning of people from different cultures?
- Do people from different cultures accept the same assessment procedures as effective ways of communicating information?
- What can we learn from comparisons of assessment data obtained from people of different cultures?
- Can mental health professionals learn to distinguish characteristics that are specific to individuals from stereotypical characteristics of particular cultural groups?

To answer these questions, systematic research is needed to compare the results of standardized assessment procedures applied to representative samples of people from different cultures. As detailed later, a growing body of research is available to answer these questions for diverse cultures. Such research can also help us distinguish between aspects of psychopathology that are relatively consistent versus those that are more variable across cultures. Throughout this chapter, we highlight the importance of comparing findings for people who differ in culture and developmental level, as they are assessed from different perspectives, to identify important consistencies and differences in levels and patterns of psychopathology.

DEVELOPMENTAL PSYCHOPATHOLOGY

Developmental approaches to the study of psychopathology have become increasingly influential over the past 3 decades. These approaches have greatly advanced our understanding of maladaptive functioning in childhood and adolescence. Developmental approaches to psychopathology have also helped to shape training and practice. However, much remains to be done to integrate the study, prevention, and treatment of psychopathology with the study of development across the life span.

Assessment, taxonomy, and diagnosis are central foci around which developmental approaches to psychopathology can be organized. As a preface to considering assessment, taxonomy, and diagnosis, it is first important to introduce what we mean by *development* and *psychopathology*. We use both of these concepts broadly, with a minimum of theoretical assumptions. Although particular theories of development and psychopathology may help us understand particular phenomena, the utility of these concepts would be diminished by limiting their meanings to the tenets of particular theories.

The Developmental Component

We use *developmental* to encompass processes, changes, sequences, and characteristics that are typically associated with age. Chronological age (CA) is the most obvious developmental yardstick, but it may serve as a proxy for many other developmental parameters. For some purposes, it may be preferable to use other developmental parameters that do not necessarily correlate highly with CA. Mental age and other indexes of cognitive developmental level, for example, would not correlate highly with CA in samples that included children with mental retardation, whose cognitive levels would be below their CAs, or very bright children, whose cognitive levels would be above their CAs. Biological parameters are also important developmental indexes. Nevertheless, even when a parameter other than CA provides a more precise index of developmental variables, CA remains an important common denominator because of CA-related differences in biological maturity and social status. Our use of the term *developmental* is intended to stimulate new ideas rather than to mold thinking according to the dictates of any single concept of development.

In addition to identifying characteristics that are associated with particular developmental parameters, a developmental perspective focuses on adaptation. By identifying adaptive and maladaptive processes, we can shed light on the origins of favorable versus unfavorable outcomes. This, in turn, provides a basis for inferring causal factors in psychopathology and for interventions to prevent or treat psychopathology by enhancing factors that lead to favorable outcomes.

Developmental Theories

Some of the most influential theories of human psychological functioning have been developmental. Psychoanalytic theory, for example, interprets adult psychopathology in terms of childhood precursors involving psychosexual stages, fixations, and regressions (S. Freud, 1940). Piaget's (1983) theory portrays adult cognitive functioning as an outgrowth of stage-like advances and reorganizations. Learning theories attribute deviant behavior to the environmental contingencies experienced throughout the individual's lifetime (e.g., Bandura, 1977). Theories about infants' attachment to their caregivers have been used to explain later interpersonal functioning in terms of persisting attachment representations (e.g., Cassidy & Shaver, 1999). Genetic theories hypothesize sequences of biological determinants that start at conception and continue through the eventual emergence of psychopathology (Rutter, 1991).

Because different theories can help us understand different aspects of development and psychopathology, the developmental study of psychopathology should not be restricted to the tenets of any single theory.

It may seem obvious that an organism's behavior at a particular point is in many respects an outgrowth of its previous history. It is much less obvious how and to what extent the organism's previous history determines successful adaptation versus pathological maladaptation at particular points. The diverse theories attest to the range of possible ways to view development and to the multitude of variables that may be associated with differences in developmental periods and levels. Although it is not feasible for us to take account of all variables posited by all theories of development, the different theories provide rich arrays of clues and concepts for guiding the developmental study of psychopathology.

Developmental Considerations in Assessment, Taxonomy, and Diagnosis

Knowledge of development should guide assessment, taxonomy, and diagnosis of psychopathology. For example, knowledge of cognitive development would argue against using interviews that require children to judge their own behavioral and emotional problems before they are cognitively capable of making and communicating such judgments. Although this may seem obvious, Breton et al. (1995) found that even normal 9- to 11-year-olds failed to understand many questions on the Diagnostic Interview Schedule for Children (DISC; Shaffer, 1992), which is widely used to make psychiatric diagnoses. Knowledge of development is thus needed to tailor assessment methods to the specific capabilities of those who are being assessed. Assessment should also be designed to detect possible developmental differences that have not previously been identified.

In designing assessment procedures to take account of developmental differences, it is important to be sensitive to developmental variations in the *content* and *patterning* of the relevant phenomena, as well as to parameters that can be measured in a uniform fashion across broad age spans. For example, height, weight, and IQ are expressed in numbers for people of all ages. Yet, the physical and cognitive configurations underlying these numbers change markedly across the life span. Thus, children who weigh 40 pounds at age 5 and 120 pounds at age 15 have not merely grown three times as large; their body proportions have changed, pubertal development has occurred, and their adolescent appearance causes people to treat them differently.

Analogously, the cognitive processes and specific responses that yield an IQ of 100 at age 5 are very different from those that yield an IQ of 100 at age 15. By the same token, psychopathological conditions that bear the same diagnostic label at different ages, such as Attention-Deficit/Hyperactivity Disorder (ADHD), may be phenotypically quite different at ages 5, 15, and 30, may involve different underlying processes, and may have different consequences for the individual's adaptation. We should therefore be aware that when diagnostic terms such as ADHD are applied to people of different ages, they may not actually represent encapsulated disorders that are the same at all ages.

We must also remember that certain behaviors may be considered normal during one developmental period but deviant at earlier or later developmental periods. For example, high levels of motor activity that are normal for preschoolers would be considered deviant in adolescents. Conversely, degrees of sexual interest that are normal for adolescents would be considered deviant for preschoolers.

Developmental Methodology

Developmental approaches contribute methodology that is essential for comparing functioning at different ages and for linking variables assessed at one age with those assessed at other ages. Longitudinal research is a hallmark of developmental methodology and is essential for determining relations between variables assessed at different ages. Certain classic longitudinal studies have had major impacts on views of relations between childhood characteristics and broad aspects of later functioning (e.g., Bayley, 1968; Kagan & Moss, 1962). Others have revealed developmental relations between childhood characteristics and adult psychopathology (e.g., Hofstra, van der Ende, & Verhulst, 2002a, 2002b; Krueger, Caspi, Moffit, & Silva, 1998).

Despite their importance, real-time longitudinal studies are costly, seldom use broadly representative samples, and take many years to yield results. More practical methods for obtaining longitudinal data have therefore been sought. These include follow-up (or catch-up) studies, in which people assessed at one age are sought for reassessment at a later point in time, and follow-back studies, which seek to obtain records of the earlier history of people for whom outcomes are known. Follow-up and follow-back studies are usually quicker and more economical than real-time longitudinal studies. Follow-up and follow-back designs may also be used to select individuals who have particular risk or outcome characteristics that would be difficult to study with real-time longitudinal designs because of obstacles to repeatedly assessing large enough samples of such individuals.

Examples of influential follow-up studies of childhood disorders include Robins's (1966) study of adults who had been assessed at a child guidance clinic many years earlier and a long-term follow-up of autistic children by Kanner, Rodriguez, and Ashenden (1972). Follow-back studies that started with known adult outcomes include comparisons of the early school records of people who differed in adult psychiatric diagnoses (Lewine, Watt, Prentky, & Fryer, 1980).

Because longitudinal research is essential for linking early characteristics with later outcomes, it is important to consider strategies for applying longitudinal methodology. In later sections, we present research designs that are especially useful for illuminating the developmental course of psychopathology.

The Psychopathology Component

We use the term *psychopathology* broadly to encompass persistent behavior, thoughts, and emotions that are likely to impede the accomplishment of developmental tasks necessary for long-term adaptation. For children, the important developmental tasks include at least the following: regulation of biological functions relevant to eating, sleeping, elimination, and energy expenditure; maintenance of close relationships with family and peers; acquisition of academic and social skills; preparation for adult occupational and social roles; and formation of a stable sense of personal identity. For adults, important developmental tasks include achievement of mature occupational and social roles; establishment of close relationships with other adults; responsible citizenship; and, for those who have children, responsible parenthood and creation of loving, healthy home environments. For older adults, important developmental tasks include constructive coping with the aging process; changing or giving up occupational roles; facing the loss of friends and loved ones, as well as one's own demise; maintaining a sense of independence; and preserving close attachments without becoming burdensome.

A key aim of this chapter is to advance our ways of thinking about psychopathology. Because psychopathology can be conceptualized in different ways for different purposes, it is important to consider the relative utility of various models for assessment, taxonomy, and diagnosis.

Nosologically Based Models

Nosological models for psychopathology originated in the nineteenth century with efforts to bring psychopathology out of the realm of demonology and into the realm of phys-

ical medicine. An important thrust of these efforts was to model the classification of mental disorders on classifications of diseases, which are called *nosologies*.

Contemporary psychiatric nosologies stem largely from Emil Kraepelin's (1883) efforts to construct descriptive categories of major adult disorders for which, Kraepelin hoped, different physical causes would eventually be found. Kraepelin's nosology included diagnostic categories such as Schizophrenia (originally called dementia praecox, that is, premature or early dementia) and manic-depressive (bipolar) disorder, which have remained cornerstones of psychiatric nosologies ever since. Kraepelin's nosology was intended to be "descriptive" in the sense of being based on observations of patients. For adult disorders characterized by extreme forms of behavioral, emotional, and cognitive deviance, such as Schizophrenia and bipolar disorders, Kraepelin's descriptive approach established diagnostic categories that still survive. Furthermore, some disorders that were initially described in terms of both mental and physical abnormalities were eventually found to have specific physical causes. An example is general paresis, which involves mental and physical deterioration that by the late nineteenth century was found to be caused by syphilitic infection. Another example is Down syndrome, which Langdon Down (1866) described in terms of mental retardation and physical abnormalities, although it was only in 1959 that the cause was found to be a chromosomal abnormality (Lejeune, Gautier, & Turpin, 1959).

Efforts to describe disorders clinically and then to find physical etiologies have thus yielded some notable successes. Early success in discovering the etiology of paresis helped to establish the physical disease model for psychiatric nosology. Alternatively, success in pinpointing the etiology of Down syndrome had to wait for nearly a century of advances in genetic research.

Kraepelinian diagnostic categories have long molded clinical practice, theory, training, and funding for research and services. In the United States, versions of Kraepelinian nosology have been embodied in successive editions of the American Psychiatric Association's (1952, 1968, 1980, 1987, 1994) *Diagnostic and Statistical Manual of Mental Disorders* (DSM-I, DSM-II, DSM-III, DSM-III-R, DSM-IV). At the international level, the *International Classification of Diseases* (ninth edition, ICD-9; tenth edition, ICD-10; World Health Organization, 1978, 1992) has also embodied versions of Kraepelinian nosology.

The "Top-Down" Strategy. In applying current versions of nosologically based models, experts formulate

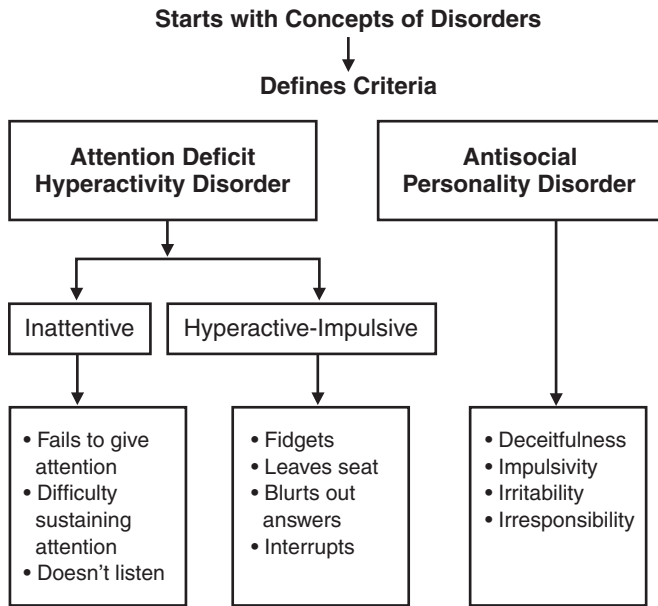

Figure 5.1 The “top-down” approach to assessment and taxonomy of psychopathology. Copyright by T. M. Achenbach. Reproduced by permission.

diagnostic categories and then choose criteria with which to define the categories. In effect, the experts start at the top with categories and then work down to the criteria, as illustrated in Figure 5.1. The diagnostic criteria for some disorders state that symptoms and impairment must be present in more than one context. However, the nosologically based paradigm does not provide specific assessment operations for obtaining and coordinating data from multiple sources. Instead, for each case, the diagnostician decides what data to obtain, what assessment methods and sources to use, and how to combine data into yes-or-no decisions about each symptom. The diagnostic data may thus differ greatly from case to case, but the same fixed decision rules are used to make diagnoses for both genders and all ages.

Empirically Based Models

For disorders having no known physical cause, an alternative to nosologically based models is to use statistical procedures to identify problems that tend to co-occur in large samples of people. Sets of statistically co-occurring problems are known as *syndromes*. (The original Greek meaning of “syndrome” was “the act of running together”; Gove, 1971, p. 2320.) The empirical identification of syndromes does not imply any assumptions about the cause of the syndromes. Some syndromes may ultimately be found to have physical causes, and others may be found to have experiential causes or combinations of physical and experiential causes.

Efforts to develop empirically based models for child psychopathology began during the 1940s and 1950s in reaction to the lack of diagnostic categories for childhood disorders (e.g., Hewitt & Jenkins, 1946; Himmelweit, cited in Eysenck, 1953). The advent of powerful computers in the 1960s facilitated factor analysis of large pools of problem items scored for large samples of children (Achenbach, 1966; Miller, 1967; Quay, 1964). The syndromes identified by factor analysis are scored by summing the scores for the problem items that compose a syndrome. Because the empirically based approach uses statistical analyses to aggregate problems that are then scored in terms of syndromes, it is also known as the *dimensional, quantitative, or multi-variate* approach.

The “Bottom-Up” Strategy. The empirically based approach can be described as working from the bottom up, because it starts with quantitative scores for many specific problems obtained for many individuals from informants who see them under diverse conditions. The item scores are then analyzed statistically to identify syndromes of problems that tend to occur together, as illustrated in Figure 5.2. A score for each syndrome scale is computed by summing the scores of the items that compose the scale. Norms for the syndrome scales are then constructed from data obtained for large representative samples of people.

Variations on the Bottom-Up Strategy. In addition to empirically derived syndrome scales, numerous scales have been constructed according to criteria other than empirically identified associations among problems, even though factor analysis may have been employed as well. As an example, the Behavior Assessment System for Children was developed from an initial set of constructs chosen by Reynolds and Kamphaus (1992). Collections of items were

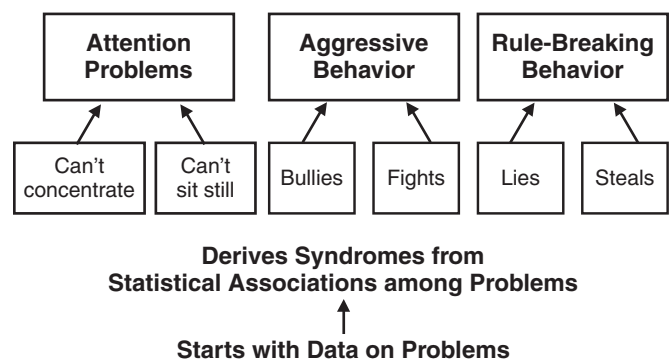

Figure 5.2 The “bottom-up” approach to assessment and taxonomy of psychopathology. Copyright by T. M. Achenbach. Reproduced by permission.

written to conform to definitions of the constructs. An item was assigned to a scale if it was “clearly linked in terms of content to the construct underlying its scale” (p. 72). Although factor analyses were performed, items were moved or deleted from the obtained factors on the basis of “reasonableness of content for the hypothesized scale dimension”; “consistency of item placement across age levels and . . . between parent and teacher respondents”; “the need for each scale to have a sufficient number of discriminating items to be reliable”; and “clinical judgment” (pp. 72–73). As an example of clinical judgment, Reynolds and Kamphaus stated that “The rating scale item ‘Says “I want to die” or “I wish I were dead”’ was retained on the Depression scale despite low loadings because of its clear relevance” (p. 73). Also, “Several pairs of final scales initially were part of a single scale. Examples include Depression/Withdrawal and Hyperactivity-Attention Problems” (p. 80).

Theoretically Based Models

There has been abundant theorizing about the nature of particular disorders and also about the nature of psychopathology in general. Nineteenth-century nosological efforts were initially based on the theory that all mental disorders are caused by brain diseases (Griesinger, 1845/1867). Kraepelin’s (1883) initial aim was to describe differences among disorders for which different physical causes were expected to be found. However, by the 1915 version of his nosology, Kraepelin included disorders thought to be of psychological origin. He also included personality disorders, which he viewed as occupying a border region between illness and eccentricity. Although subsequent psychiatric nosologies have continued to be modeled on nosologies of physical diseases, they have not been dictated by any single etiological theory.

The Psychoanalytic Model. Historically, the most influential general theory of psychopathology has been psychoanalysis. Sigmund Freud (1917/1963) proposed theoretical explanations for the development of particular disorders such as obsessive-compulsive versus hysterical neurosis. With respect to childhood disorders, Anna Freud (1965) proposed a Developmental Profile for assessing individual children in terms of developmental sequences hypothesized by analytic theory. The Developmental Profile includes diagnostic categories specified in terms such as the following: “There is permanent drive regression to fixation points which leads to conflicts of a neurotic type” (p. 147). Little has been published on how children are to be distinguished with respect to the assessment criteria or

diagnostic categories of the Developmental Profile. Instead, most publications illustrate how a Developmental Profile might be completed for a particular child (e.g., Yorke, 1980).

The Group for the Advancement of Psychiatry Classification. Another theoretically based model for childhood disorders was proposed by the Group for the Advancement of Psychiatry (GAP; 1966). The GAP classification was described as being designed to operationally define disorders with a minimum of inference (p. 209). Although the GAP classification provided far more categories than Anna Freud’s Developmental Profile, many of its categories required extensive psychodynamic inferences, and no assessment operations were actually specified for determining whether a child met the criteria for particular categories. As an example, the GAP category of Psychoneurotic Disorders was defined as:

disorders based on unconscious conflicts over the handling of sexual and aggressive impulses which, though removed from awareness by the mechanism of repression, remain active and unresolved. . . . The anxiety, acting as a danger signal to the ego, ordinarily sets into operation certain defense mechanisms, in addition to repression, and leads to the formation of psychological symptoms which symbolically deal with the conflict, thus achieving a partial though unhealthy solution. (pp. 229–230)

A FRAMEWORK FOR THE DEVELOPMENTAL STUDY OF PSYCHOPATHOLOGY

To advance the developmental study of psychopathology, it is helpful to have a clear framework of issues to be addressed. Because no single research study can simultaneously address all the issues, programmatic research to improve the assessment, taxonomy, and diagnosis of psychopathology is needed to resolve these issues.

Developmental Differences

We previously stressed the importance of developmental parameters in all research on psychopathology. To obtain an accurate picture of psychopathology, it is essential to gear assessment procedures to the developmental level of the participants, to determine what features are associated with clinical deviance at each level, and to construct taxonomies that reflect features characterizing each developmental level. The features that discriminate between forms

of deviance are apt to change with development. It is therefore important for assessment and taxonomy to take account of developmental changes occurring in individuals, so that the same individuals can be studied longitudinally. Both the differences and the links between developmental levels should be rigorously tested.

Sources of Data

Stemming largely from nosological models, clinical interviews have long been the main sources of data for assessing adult psychopathology. Beginning in the 1970s, structured diagnostic interviews were developed to obtain yes-or-no decisions about whether adult patients met specific research diagnostic criteria (RDC) for major mental disorders, such as Schizophrenia and manic-depressive psychoses (e.g., Overall & Hollister, 1979). The structured interviews included the Schedule for Affective Disorders and Schizophrenia (SADS; Endicott & Spitzer, 1978) and the Diagnostic Interview Schedule (DIS; Robins, Helzer, Croughan, & Ratcliff, 1981).

The explicit criteria and decision rules embodied in various versions of RDC laid the foundations for *DSM-III* (American Psychiatric Association, 1980). Departing from the narrative-inferential format of *DSM-I* and *DSM-II* (American Psychiatric Association, 1952, 1968), *DSM-III* defined disorders in terms of lists of symptoms and other criteria, such as age of onset and duration of the symptoms. When using *DSM-III* and its successors, *DSM-III-R* and *DSM-IV* (American Psychiatric Association, 1987, 1994), the diagnostician is to make a yes-or-no decision about whether a patient meets each of the criteria required for a particular disorder. If the patient is deemed to meet all the requisite criteria, the patient is diagnosed as having the disorder. Diagnostic criteria and decision rules have thus become far more explicit than those provided by *DSM-I* and *DSM-II*. However, neither *DSM-III* nor its successors have specified assessment operations for determining whether the diagnostic criteria are met, except for specifying that an IQ score of 70 or lower is required for diagnosing mental retardation. As one approach to operationalizing *DSM* diagnostic criteria, the structured interviews that had been developed in the 1970s to make RDC diagnoses were subsequently revised to conform to *DSM-III* (e.g., Robins, Helzer, Ratcliff, & Seyfried, 1982; Spitzer, 1983).

Multi-Informant Data for Children

Some of the structured diagnostic interviews for adults were modified for diagnosing children. Examples include the Kiddie-SADS (Ambrosini, 2000; Puig-Antich & Chambers,

1978), which is a child version of the SADS (Endicott & Spitzer, 1978), and the Diagnostic Interview Schedule for Children (DISC; Costello, Edelbrock, Dulcan, Kalas, & Klaric, 1984; Shaffer et al., 1996), which is a child version of the DIS (Robins et al., 1982). Because it was recognized that children may not be able to provide full accounts of their own psychopathology, versions of the structured child interviews were also developed to obtain diagnostic information from the children's parents (e.g., DISC-P; Costello et al., 1984; Shaffer et al., 1996).

Unfortunately, the parallel structured diagnostic interviews for children and their parents did not solve problems arising from children's inability to give full accounts of their own psychopathology. Numerous studies have found little agreement between *DSM* diagnoses made from DISC interviews with children (including adolescents) and those made from interviews with their parents (e.g., Costello et al., 1984; Shaffer et al., 1996; Verhulst, van der Ende, Ferdinand, & Kasius, 1997). Furthermore, little agreement has been found between diagnoses obtained from structured child and parent interviews and clinicians' diagnoses based on other data (e.g., Costello et al., 1984; A. L. Jensen & Weisz, 2002; Lewczyk, Garland, Hurlburt, Gearity, & Hough, 2003; Rettew, Achenbach, Doyle, Ivanova, & Dumenci, 2005).

Perhaps we should not be surprised by the poor agreement between diagnoses made from structured interviews of children and their parents, or between these interviews and diagnoses made by clinicians who use other data. When asked to give yes-or-no answers to questions about psychopathology, children and their parents are apt to draw on different perceptions and memories of the children's functioning; to be differently motivated to report, distort, or withhold information; to understand questions differently; and to be differently affected by interviewers and the interview situation. Clinicians are also apt to differ from children and parents with respect to their information about the children, their memories of the information, how they combine pieces of information, and how they generate responses to questions about diagnoses.

Meta-analyses of many studies have yielded a mean r of .60 between reports of children's problems by people who play similar roles with respect to the children, such as pairs of parents, pairs of teachers, pairs of mental health workers, and pairs of observers (Achenbach et al., 1987). Between pairs of informants who play different roles with respect to the children, such as parents versus teachers and parents versus mental health workers, the mean r was .28. And between children's self-reports and reports by other people, the mean r was .22. These modest cross-informant r s indicate that diagnoses of children are likely to vary

with the source of the data and that no one informant can substitute for all others.

Multi-Informant Data for Adults

Although the need for multi-informant data to assess child psychopathology is now widely recognized, assessment of adult psychopathology still relies mainly on interviews with the adults themselves. Yet, research shows that diagnoses based only on interviews with the adults in question are not likely to agree with diagnoses based on other sources of data. For example, studies of agreement between adults' self-reports of problems and reports by people who know the adults have yielded average correlations in the .20s to .40s (Achenbach et al., 2005; Klonsky, Oltmanns, & Turkheimer, 2002; Meyer, 2002; Meyer et al., 2001). In reviewing numerous studies of diagnoses of adult psychopathology, Meyer et al. concluded, "There was meager correspondence between diagnoses derived from a single clinician using (clinical interviews) and the diagnoses derived from the multimethod evaluations . . . after correcting for agreements due to chance, about 70% of the interview-based diagnoses were in error" (p. 151). Furthermore, even when the same adults were interviewed twice, once by trained lay interviewers using the DIS and once by psychiatrists using the Schedules for Clinical Assessment in Neuropsychiatry, agreement between the two interviews was extremely low, as exemplified by a kappa = .20 for Major Depressive Disorder (Eaton, Neufeld, Chen, & Cai, 2000).

For elderly adults whose mental competence is in question, it is common to obtain data from people who know the elders, such as spouses, grown children, and caregivers. The need to obtain information from others argues for routine use of parallel assessment instruments that have been developed to obtain and systematically compare assessment data from multiple informants regarding the functioning of elderly people (Achenbach, Newhouse, & Rescorla, 2004).

In adopting life span perspectives on psychopathology, we should apply lessons already learned about needs and methods for cross-informant assessment of children to assessment of adults and the elderly. The aspects of functioning to be assessed, the sources of data, and the assessment instruments must, of course, be geared to the developmental levels of the people who are being assessed.

Epidemiological Aspects

Many studies of development and psychopathology employ samples chosen for convenience rather than for representa-

tiveness with respect to important populations. This is understandable in light of the need to find people who are willing and able to participate in a particular study. However, convenience samples are often biased by selective factors that make them unrepresentative of populations. As a result, the distributions of variables and the findings in such samples cannot necessarily be generalized to other people.

If our knowledge of psychopathology is derived mainly from people who are conveniently available, we may be misled by problems that are of low frequency, do not actually distinguish normal from deviant individuals, or have different meanings among people who are not included in the convenience samples.

As an example, both the early psychoanalytic and behavioral literatures used children's fears of animals to model theories of the etiology and treatment of psychopathology. In a famous and influential case study, Sigmund Freud (1909/1953) devoted a 145-page article to illustrating the psychodynamics of Little Hans's horse phobia. In the behavioral tradition, Watson and Rayner (1920) experimentally conditioned Little Albert to fear a white rat, and Jones (1924) used Watson's principles to treat 2-year-old Peter's fear of a white rabbit.

Both the psychodynamic and behavioral traditions thus made children's fears paradigmatic for the subsequent literature on psychopathology. Yet, epidemiological studies have shown that fears of specific animals, situations, or places (other than school) are not actually much more common among children considered to be clinically deviant than among representative samples of nonreferred children (Achenbach, Howell, Quay, & Conners, 1991; Achenbach & Rescorla, 2001). Epidemiological research has also shown that specific fears are reported for *fewer* clinically referred than nonreferred adults (Achenbach & Rescorla, 2003).

Other epidemiological findings have indicated that some problems employed as criteria for nosological categories are not reported more often for clinically referred than nonreferred children. "Always on the go," for example, was a criterial symptom for the *DSM-III* category of Attention Deficit Disorder and is also a criterial symptom for the *DSM-IV* category of ADHD (American Psychiatric Association, 1980, 1994). Yet, this item was endorsed more often for a nationally representative sample of *nonreferred* children than for demographically matched *referred* children (Achenbach et al., 1991). Other nosological criteria have likewise been chosen without epidemiological evidence that they actually discriminate between clinical and non-clinical populations.

Diagnoses of behavioral and emotional disorders seldom depend on a single deviant characteristic. Instead, most

disorders involve problems that many people manifest in some degree at some time in their lives. To identify people as being clinically deviant, we therefore need to know the distribution of particular problems among people considered to be relatively normal, as well as among those who are considered deviant enough to need professional help. Because many selective factors affect referral to a particular setting, we also need data on people who are seen in different settings. And we need to know the outcomes of particular problems in both referred and nonreferred populations. This requires that epidemiological samples be reassessed longitudinally to determine which problems have relatively good versus poor outcomes when treated versus untreated and what other variables predict outcomes. Such research is important not only to determine what problems distinguish people who need help from those who do not, but also to identify risk and protective factors on which preventive and therapeutic efforts can be based.

Multivariate Aspects

Because so many different kinds and degrees of problems may evoke concern, it is important to standardize the recording and analysis of problems. The difficulty of assessing and aggregating multiple problems in large samples argues for using multivariate approaches to aggregating and analyzing standardized data. Each score for an individual problem obtained from self-reports, informants' reports, observations, or tests is subject to sampling and measurement error. However, by using multivariate statistical methods, we can aggregate scores on numerous problems from multiple sources to identify patterns that characterize groups of people. This is analogous to computed tomography (CT) scanning, where numerous low-grade X-ray pictures are integrated by computer to produce high-grade images. Once we identify patterns of problems, we can use them to group people for research on the etiology, course, prognosis, and effectiveness of treatment for each pattern. Those multivariate patterns that are found to be reliable and to validly discriminate between people who differ in other important ways can then serve taxonomic functions, as detailed in later sections.

Operational Definitions

Operational definitions of variables provide basic tools for scientific research. Although scientific thought and theory also involve abstractions that are not operationalized, empirical tests of scientific ideas typically involve variables that are specified in terms of assessment operations. The

results of the assessment operations provide the empirical content of the science.

Discussions of psychopathology are replete with terms that are used as if their meaning were self-evident. Terms (and their abbreviations) such as Conduct Disorder (CD), Oppositional Defiant Disorder (ODD), Antisocial Personality Disorder (APD), and ADHD are common examples from the *DSM* nosology. Terms such as Emotionally Disturbed (ED) and Learning Disabled (LD) are used with similar aplomb in special education circles, reflecting the influence of Public Law 94-142 (PL 94-142), the Education of the Handicapped Act (1977, 1981), which specifies eligibility for special education services (reauthorized as PL 101-476, Individuals with Disabilities Act, 1990; PL 105-17, 1997).

The need for operational definitions has been acknowledged in efforts to improve nosologies. In their diagnostic classification of childhood disorders, GAP (1966, p. 209), for example, "attempted to set forth operational definitions of clinical categories." *DSM-III* and its successors have also been heralded as providing operational definitions (e.g., Rapoport & Ismond, 1996, p. 13). However, neither the GAP classification nor the *DSM* has defined behavioral and emotional disorders according to specific assessment operations. But what about the *DSM*'s lists of explicitly stated criteria that are required for particular diagnoses? These criteria do not constitute operational definitions, because no operations are specified for determining whether a person manifests each criterial feature. Nor are operations specified for combining assessment data from multiple sources. This lack of truly operational definitions for disorders may be one reason reliability and cross-informant agreement are low for GAP and *DSM* diagnoses (e.g., Beitchman, Dielman, Landis, Benson, & Kemp, 1978; Freeman, 1971; A. L. Jensen & Weisz, 2002; Lewczyk et al., 2003; Shaffer, Fisher, Lucas, Dulcan, & Schwab-Stone, 2000).

Categories such as those specified by the *DSM* and PL 101-476 serve important administrative functions, such as providing guidelines for reimbursement of services. However, these categories were not derived from empirical findings on distinctions among disorders in actual samples of troubled people. The categories should therefore not be mistaken for "types" of people or "types" of disorders. Although people may indeed have the kinds of problems highlighted by administrative categories, people do not necessarily come packaged according to these categories. That is, we should not assume that people are intrinsically ADHD, CD, ODD, APD, ED, or LD. Unless we empirically test (1) the associations among features that are used to de-

fine the categories and (2) the power of the features to discriminate between normal and troubled people, we cannot know how best to distinguish among kinds of disorders. To improve our ability to distinguish between normal and clinically deviant people, as well as among patterns of clinical deviance, we need programmatic research that yields more robust groupings than most administrative categories have provided. Such research is needed to advance our overall understanding of psychopathology as well.

THE ROLES OF ASSESSMENT AND TAXONOMY IN THE DEVELOPMENTAL STUDY OF PSYCHOPATHOLOGY

To improve our ways of distinguishing the normal from the deviant and one kind of deviance from another, it is helpful to distinguish between two related tasks. One task is to *assess individual cases* to identify their distinguishing features. The second task is to *construct taxonomies* for grouping cases according to their distinguishing features. These tasks are essential steps in identifying the target disorders to be studied in each developmental period. They also form the basis for diagnostic decisions about individual cases. To improve diagnostic decision making, we need reliable and valid procedures for identifying the distinguishing features of individual cases, for grouping cases according to their distinguishing features, and for effectively integrating all the relevant data into optimal decisions. To clarify the different tasks, we first address assessment and taxonomy as scientific endeavors that can be better understood if we avoid the multiple meanings of the term “diagnosis,” which we address later.

Although diagnosis is an essential part of clinical services, scientific efforts are needed to improve both diagnosis and its links to services. The following sections therefore focus on the scientific process, which “proceeds in endless cycles of observation and measurement, hypothesis testing, and the development of theory, a process dependent on a valid system of classification or taxonomy” (McClellan & Werry, 2000, p. 19).

Assessment

Assessment refers to gathering data with which to identify the distinguishing features of individual cases. Every case can be distinguished from other cases in many ways. Effective assessment requires selecting optimal features for the kinds of decisions to be made. To know what features are likely to be optimal, we need data from representative sam-

ples of cases for which the distributions, validity, and utility of various features have been tested.

Psychometric principles provide guidance for determining the methodological adequacy of assessment data. As applied to the assessment of behavioral/emotional problems, these principles can be summarized as follows:

- Assessment should employ standardized procedures.
- Multiple items should be used to sample each aspect of functioning.
- Items should be aggregated to provide quantitative scores for each aspect of functioning.
- Scores should be normed to indicate how an individual compares with relevant reference groups.
- To be developmentally sensitive, the normative reference groups should be formed according to age levels or other indexes of development.
- To be considered psychometrically sound, assessment procedures must be reliable and valid, although the types of reliability and validity vary with the type of procedure.

In addition to these principles, psychometric theory prescribes specific standards for constructing sound assessment procedures. Psychometric theory does not, however, tell us *which* of the many features of individual cases should be assessed. Instead, we should select features that are found to discriminate between people whose behavioral/emotional problems differ with respect to etiology, course, prognosis, and/or the most appropriate intervention. To determine which features specifically discriminate between people according to these variables, research is needed to test the discriminative power of various features. Rather than attempting to test every possible feature one by one, it is preferable to identify sets of features that tend to co-occur. Because assessment of each feature is subject to unique sources of variance, scores for sets of covarying features are likely to be more reliable than scores for individual features. Furthermore, sets of covarying features are likely to be more useful than individual features for generating and testing hypotheses, as well as for managing individual cases. The task of aggregating covarying features into sets with which to identify similar cases is the task of taxonomy, to which we now turn.

Taxonomy

It is helpful to distinguish between classification in general and taxonomy in particular. *Classification* refers to any systematic ordering of phenomena into classes, groups, or

types. Many classifications are constructed merely for the convenience of users. Administrative classifications, for example, are designed to meet particular organizational needs. The people who design such classifications may start with knowledge of the organization's needs and the ways prospective users of a classification customarily view the phenomena to be classified. They then attempt to mesh the users' classificatory behavior with the needs that the classification is to meet.

As an example, health insurers construct their own classifications of disorders to specify reimbursements for mental health services. A key question is whether a particular classification scheme enables the insurer's actuaries to compute costs accurately enough for the insurer to charge rates that are competitive but high enough to be profitable after covering all costs. For third-party payers that are not funded by premiums based on costs, such as Medicaid, the problem is complicated by unpredictable changes in the size and nature of the covered population, variations in the mental health services obtained, providers' techniques for coping with low reimbursement rates, and the vicissitudes of government funding. Considering the variety of factors that affect third-party payers' classification schemes, it is no wonder that so many classifications have been devised for reimbursement of mental health services.

In contrast to the broad concept of classification, *taxonomy* refers to a subset of classifications that are intended to reflect intrinsic differences between cases assigned to different classes. Taxonomies of plants and animals, for example, are based on features that are intended to capture important differences among species. Various features can be chosen to distinguish among groups of plants and animals, such as physical characteristics, interbreeding, and hypothesized evolutionary relations. Although the concept of species is so familiar as to seem self-evident, species is not an intrinsic property of living things. Instead, species is a taxonomic construct that is imposed on subsets of features, such as having four legs or laying eggs. Certain features are selected from all the features that might be used to distinguish among individual plants and animals (Levin, 1979). Taxonomic constructs such as species reflect distinctions based on scientifically identified intrinsic characteristics of groups of individuals, rather than reflecting distinctions that are not based on intrinsic differences among groups of individuals.

Are Behavioral and Emotional Disorders "Natural Kinds"?

Zachar (2000) has distinguished between taxonomies that consist of *natural kinds* and those that consist of *practical*

kinds. He defined a natural kind as "an entity that is regular (nonrandom) and internally consistent from one instance to the next" (p. 167). Examples include naturally occurring elements such as gold. By contrast, practical kinds "are stable patterns that can be identified with varying levels of reliability and validity" (p. 167).

Zachar (2000) argues that psychopathology is better viewed in terms of practical kinds than natural kinds. Although some may believe that taxonomies of psychopathology should identify natural kinds, both the empirically based approach and the version of the nosologically based approach embodied in *DSM* focus on practical kinds. In other words, they both define taxa in terms of sets of features no one of which is both necessary and sufficient to classify an individual's problems as belonging to a particular taxon. Both approaches are thus *polythetic* in the sense of specifying sets of features from which various subsets of the features can qualify an individual for a taxon.

Constructing Taxonomies of Behavioral and Emotional Problems

In constructing taxonomies of behavioral and emotional problems, we should be aware that the problems can be aggregated according to different taxonomic principles. Certain taxonomic principles may be useful for one stage of knowledge or for one stage of development but not for other stages of knowledge or development. Furthermore, different taxonomic principles may be useful for different kinds of disorders or for different purposes at the same stage of knowledge or for the same developmental stage. Cognitive measures, for example, may be useful for grouping people according to educability, whereas measures of behavior problems may be useful for grouping the same people for management purposes.

We also need to be aware that the features chosen to characterize cases represent abstractions with which to link cases that are expected to be similar in other important ways. When we abstract a subset of features from the many features that could be identified, we form a hypothetical construct of the case—a conceptual abstraction intended to capture the important aspects of the case. If our notion of the individual case and our grouping of cases according to certain shared features both involve hypothetical constructs, how should we match our construct of the individual case to the constructs of a taxonomy? Answers to this question must take account of both the methodological possibilities for assessing individual cases and the mental processes involved in matching the

features of the individual case to the features used to define taxonomic groupings of cases.

Prototypes as Taxonomic Models

Classification systems have traditionally defined categories in terms of criteria that are “singly necessary and jointly sufficient” for classifying individual cases (Cantor, Smith, French, & Mezzich, 1980, p. 182). That is, a case was assigned to a particular category if, and only if, it met all the criteria for that category. Conversely, all cases that met the criteria for a particular category were ipso facto assigned to that category.

Cognitive research indicates that people’s mental use of categories does not conform to the classical model whereby cases are categorized according to features that are both necessary and sufficient. As illustrated by familiar categories such as furniture, for example, the objects that people categorize together do not all share the same defining features (Rosch & Mervis, 1975). Instead, certain objects classified as furniture, such as tables and chairs, have little similarity to other objects that are also classified as furniture, such as lamps and rugs.

Objects that have the most features of a category are considered to be the most typical of the category and are more quickly and reliably categorized than are objects that have fewer of the category’s features (Smith & Medin, 1981). For example, a sparrow is more prototypical of birds than an ostrich is. Furthermore, objects that have features of multiple categories are especially difficult to categorize reliably. As an example, a tomato is difficult to categorize as a fruit or a vegetable, because it has features of both categories.

Instead of being rigidly defined by criterial features that must all be present in all members of a category, mental representations of categories consist of sets of imperfectly correlated features known as *prototypes* (Rosch, 1978). Consequently, people judge category membership according to the degree of overlap between the features of a case and the set of prototypical features that define a category. In other words, people judge cases having many features of a prototype to be very typical of the category represented by that prototype. They judge cases that have few features of a prototype to be less typical of that category. Cases that manifest features of more than one prototype are judged to lie on the border between the categories represented by those prototypes.

According to the prototype view, people make quantitative judgments of the resemblance between particular cases

and particular categories. That is, the degree of resemblance between a case and a category is judged according to the number of prototypical features that the case shares with the category. Furthermore, if each prototypical feature of a case and of a category can be scored in terms of the intensity or certainty with which the feature is manifested, then the case’s resemblance to the category can be quantified in terms of the sum or other aggregation of scores on all the prototypical features.

If the human minds that must use taxonomies actually conceptualize categories in terms of quantifiable prototypes, why not use quantifiable prototypes in taxonomies of psychopathology? The possibilities for doing this are presented after we consider conventional diagnostic thinking.

DIAGNOSIS

The term *diagnosis* conveys an aura of clinical authority, implying that it reveals an essential truth about what is really wrong with a patient. Yet, the term has multiple meanings that sow confusion when we move from research tasks conceptualized in terms of assessment and taxonomy to clinical practice conceptualized in terms of diagnoses. To clarify relations between the research tasks and clinical practice, it is helpful to distinguish among the different meanings of diagnosis discussed next.

Diagnostic Processes

Diagnostic processes involve gathering the data needed for diagnostic decisions. Such processes are analogous to what we earlier defined as assessment. However, because diagnosis implies gathering data to determine which disease a person has, diagnostic processes connote a narrower range of possibilities than the more neutral term assessment.

Formal Diagnoses

Formal diagnoses involve assigning cases to the categories of a diagnostic classification. Accordingly, a leading psychiatric diagnostician, Samuel Guze (1978, p. 53), defined diagnosis as “the medical term for classification.” This is the sense in which the categories of the *DSM*, *GAP*, and *ICD* nosologies are diagnoses. When a clinician states that a person meets the *DSM* criteria for Conduct Disorder or Antisocial Personality Disorder, for example, the clinician is making a formal diagnosis.

Diagnostic Formulations

Diagnostic formulations are efforts to elucidate multiple aspects of an individual's condition. When a clinician interprets a person's problems in terms of physical vulnerabilities, developmental history, family dynamics, stress, and rejection by peers, for example, the clinician makes a diagnostic formulation. A diagnostic formulation should weave all the findings of the diagnostic process into a comprehensive picture of the case. The diagnostic formulation thus provides a broader basis for developing treatment plans than a formal diagnosis does. Yet, it is by means of the formal diagnosis that the individual case is linked to others like it.

The formal diagnosis helps the clinician apply existing knowledge about a class of cases to a diagnostic formulation for a new case. For knowledge about a class of cases to be accurately applied to a new case, reliable procedures are needed for gathering data, integrating data into a diagnosis, and selecting the appropriate formal diagnosis. Furthermore, the system from which the formal diagnosis is selected must be reliable, must be valid with respect to important correlates of its diagnostic categories, and must encompass cases like the one being diagnosed. In short, the credibility of diagnosis depends on the same methodological standards as assessment and taxonomy do. Diagnosis thus involves gathering data to identify the distinguishing features of individual cases and grouping cases according to their distinguishing features, just as assessment and taxonomy do. Whichever terminology is used, the value of such procedures ultimately depends on whether they help people.

Comorbidity Issues

Since the introduction of explicit diagnostic criteria by *DSM-III* (American Psychiatric Association, 1980), many people have been found to meet the criteria for more than one disorder (e.g., Costello et al., 1984; Livingston, Dykman, & Ackerman, 1990; Weinstein, Noam, Grimes, Stone, & Schwab-Stone, 1990). Termed *comorbidity*, the tendency for people to meet criteria for multiple disorders has a variety of implications. The apparent co-occurrence of two disorders could mean, for example, that one disorder results from the other, or that the same risk factors lead to both disorders, or that the two disorders are not really separate but are manifestations of the same underlying condition (Achenbach, 1991a; Caron & Rutter, 1991).

Most *DSM* and *ICD* categories are not based on evidence for the independent existence of a separate disorder for

each category. Nor do the *DSM* and *ICD* specify assessment operations for reliably discriminating between disorders. When assessment procedures have been designed to operationalize *DSM* criteria for disorders, high rates of comorbidity have often been found. For example, two studies have shown that 96% of boys who met *DSM* criteria for CD also met criteria for ODD (Faraone, Biederman, Keenan, & Tsuang, 1991; Walker et al., 1991). In addition, the *DSM-III-R* field trials found that 84% of clinic-referred children who met criteria for CD also met criteria for ODD (Spitzer, Davies, & Barkley, 1990). Because the *DSM* criteria for these disorders have not been proven to distinguish between separate entities, the very high rates of overlap between diagnoses suggest that the diagnostic criteria may be interdependent.

Unidirectional versus Bidirectional Comorbidity

The specific rates of comorbidity reported in many studies may be misleading, because they reflect computation of the overlap between diagnoses in only one direction. That is, they reflect the percentage of individuals having diagnosis A who also have diagnosis B. If diagnoses A and B have different prevalence rates in a sample, this unidirectional computation yields a different rate of comorbidity than would be obtained by computing the percentage of individuals having disorder B who also have disorder A. For example, suppose that 50 children in a sample of 100 obtain a diagnosis of CD (diagnosis A) and that 48 of these 50 obtain a diagnosis of ODD (diagnosis B). The unidirectional comorbidity of ODD (diagnosis B) among children who have CD (diagnosis A) is $48/50 = 96\%$. However, if 80 of the children have ODD, and 48 of these have CD, the unidirectional comorbidity of CD among children who have ODD is $48/80 = 60\%$. By recomputing published comorbidity rates bidirectionally (i.e., as the mean of the comorbidities of A to B and B to A), McConaughy and Achenbach (1994) obtained quite different rates from those based on the unidirectional comorbidities. When comorbidity is conceptualized in terms of the co-occurrence of two categorically defined disorders, it is thus important to consider the bidirectional rates of comorbidity between the disorders.

Berkson's Bias

Apparent comorbidity among disorders may also be misleading in other ways, as detailed elsewhere (Achenbach, 1991a; Caron & Rutter, 1991). Suppose, for example, that individuals manifesting a particular disorder have *X* probability of referral. Suppose, too, that individuals manifesting another disorder have *Y* probability of referral. Even if the

disorders do not tend to co-occur in the population as a whole, people who have both disorders have $X + Y - XY$ probability of referral. This is obviously higher than individuals who have only X or Y probability of referral. If we study only referred people, then we may conclude that the two disorders tend to occur together. Yet, if we study the entire population (including nonreferred people), we might find that the two disorders have no more than chance co-occurrence, because individuals having any one disorder without the other are much more common in the nonreferred portion of the population than in the referred portion.

Known as *Berkson's bias* (Berkson, 1946), the tendency of apparent comorbidity to be inflated by referral biases is one of many artifactual ways that findings of co-occurrence between even independently verifiable disorders can arise. The different effects of referral biases on different problems has been demonstrated by comparing comorbidities obtained among empirically based syndromes in demographically similar referred and nonreferred samples (McConaughy & Achenbach, 1994).

Implications of Comorbidity

If two disorders are operationally defined according to mutually independent assessment procedures, and if the two disorders are demonstrated to occur together with greater than chance frequency in unbiased samples of the general population, then the comorbidity of these particular disorders may be quite informative. However, if diagnoses are not based on operational definitions of empirically separable disorders, then findings of comorbidity may merely reflect a lack of clear boundaries between diagnostic categories or an inability of diagnosticians to validly distinguish between disorders that do not really co-occur with more than chance frequency.

Rather than taking findings of comorbidity at face value as reflecting the co-occurrence of two distinct disorders, we should therefore examine the diagnostic system itself for possible artifactual sources of apparent comorbidity. The high rate of overlap found between diagnoses of ODD and CD (Faraone et al., 1991; Spitzer, Davies, & Burkley, 1990; Walker et al., 1991), for example, invites scrutiny of the diagnostic system to determine whether ODD and CD truly represent separate disorders. The arbitrariness of the distinctions between the diagnostic categories of ODD and CD is highlighted by the major changes they underwent from *DSM-III* to *DSM-III-R*, with further changes in *DSM-IV*. *DSM-III* (American Psychiatric Association, 1980) listed five criteria for ODD, of which only two needed to be met for the diagnosis. *DSM-III-R* (American Psychiatric

Association, 1987), by contrast, listed nine criteria, of which five were needed for the diagnosis. *DSM-IV* lists eight criteria, of which four are needed for the diagnosis. Furthermore, the *DSM* criteria for diagnoses of CD also underwent major changes from *DSM-III* to *DSM-III-R*, with further changes in *DSM-IV*. *DSM-III* provided four distinct categories, plus a residual category of Atypical CD. *DSM-III-R*, by contrast, provided only one set of explicit criteria for CD, although once the prescribed number of criteria were met, the disorder could be categorized as "group type," "solitary aggressive type," or "undifferentiated type," according to the diagnostician's judgment. *DSM-IV* has dispensed with these types in favor of "childhood-onset type" versus "adolescent-onset type."

Classification systems should incorporate changes based on new knowledge. However, the *DSM-III-R* and *DSM-IV* revisions were not derived from empirical tests of the co-occurrence of particular features or of whether the criteria for ODD and CD actually discriminated between distinctly different disorders in representative samples of children. Furthermore, no provision was made for calibrating diagnoses made from one edition of the *DSM* with those made from previous editions. It should not be surprising, therefore, that very different distributions of ODD and CD were obtained when applying *DSM-III* versus *DSM-III-R* to the same children, and that many children met criteria for both ODD and CD (Lahey et al., 1990). *DSM-IV* diagnostic criteria yield still different distributions of these diagnoses.

DSM-III-R and *DSM-IV* specify that the diagnosis of ODD is not to be made if the criteria for CD are met. Does this mean that ODD is a mild version of CD, a developmentally early version, or a by-product? Or does it mean that the two disorders are intrinsically related in some other way? Similar questions arise from overlaps among other diagnostic categories that are not derived from actual data on relations among problems. Based on a detailed examination of these and other issues, Lilienfeld, Waldman, and Israel (1994, p. 71) cautioned that the application of the term comorbidity to psychopathology "encourages the premature reification of diagnostic entities" that have not actually been validated.

LONGITUDINAL DESIGNS FOR THE DEVELOPMENTAL STUDY OF PSYCHOPATHOLOGY

Many kinds of research designs can contribute to the developmental study of psychopathology. However, longitudinal

designs, in which the same people are assessed at two or more points in their development, provide the most direct tests of relations between developmental parameters and patterns of problems. In the following sections, we illustrate some variations on traditional longitudinal designs that may be especially useful for developmental research related to assessment, taxonomy, and diagnosis.

Accelerated Longitudinal Designs

The ability of traditional longitudinal designs to shed light on psychopathology has been limited by the difficulty of maintaining participant samples, research teams, and funding over long periods. In addition, most longitudinal studies have been handicapped by their failure to compare different birth cohorts and by their use of different assessment procedures at different ages. The latter limitations affect real-time, follow-up, and follow-back studies alike.

Life span developmental psychologists have emphasized the need to take account of differences related to birth cohorts and times of measurement, as well as differences related to age (e.g., Baltes, 1987). Unfortunately, it is difficult to include cohort and time-of-measurement comparisons in traditional longitudinal research designs.

One way to improve longitudinal research on psychopathology is to assess multiple birth cohorts by the same methods over several uniform intervals. Such designs have been variously called “convergence” (Bell, 1953, 1954), “longitudinal-sequential” (Schaie, 1965), “mixed-longitudinal” (van’t Hoff, Roede, & Kowalski, 1991), and “cohort-sequential” (Baltes, Cornelius, & Nesselroade, 1979). Because several birth cohorts are assessed in the same way over the same period, the longitudinal findings for each cohort can be compared with the findings for each other cohort. We can thus determine whether changes with age are similar in all cohorts or whether the changes differ among cohorts or times of measurement.

An additional strength of cohort-sequential designs is that they can potentially reveal developmental sequences over a longer period of time than the real time spanned by the study. For this reason, they are also called *accelerated longitudinal designs*. How can we perform this magic of accelerating longitudinal research? The logic is as follows:

- At Time 1, individuals from several adjoining birth cohorts are assessed in a uniform fashion. For example, in June 2007, a test is administered to cohorts of children who are 6, 7, 8, or 9 years old (designated as Cohorts 6, 7, 8, and 9).
- At Times 2, 3, and 4, the same test is readministered to the same children. In our example, the test is readministered in 2008, 2009, and 2010 to Cohorts 6, 7, 8, and 9, who will be 9 to 12 years old at the final administration in 2010.
- Individuals from one cohort are matched to individuals in another cohort. In our example, children from Cohort 6 are matched to children in Cohort 7 with respect to demographic variables and test scores obtained at ages 7 and 8. That is, a particular Cohort 6 middle-SES boy named Chris is matched to a particular Cohort 7 middle-SES boy named Scott whose test scores at ages 7 and 8 were similar to the scores obtained by Chris at ages 7 and 8.
- The accuracy of predicting scores obtained by individuals in one cohort from earlier scores obtained by matched individuals in another cohort is then tested. In our example, we compute the correlation between scores obtained at age 6 by Cohort 6 children and scores obtained at age 9 by their matched counterparts from Cohort 7. For purposes of comparison, we then compute the correlation between the scores obtained at age 6 by the Cohort 6 children and their own scores at age 9. Suppose the correlation between age 6 and 9 scores within Cohort 6 is significant. Suppose also that the between-cohort correlation from scores obtained at age 6 by Cohort 6 children to the age 9 scores obtained by their matched Cohort 7 counterparts is of the same magnitude as the correlation from age 6 to age 9 within Cohort 6. These findings would indicate that the score obtained at age 6 by a Cohort 6 child, such as Chris, can be used to predict the score obtained at age 9 by a Cohort 7 child, such as Scott, with as much accuracy as prediction of Scott’s age 9 score from his own age 6 score.
- If the findings outlined in the step above are replicated for the other combinations of cohorts in the study, it may become possible to create matched sets of individuals across the four cohorts to predict scores obtained by Cohort 9 at age 12 from scores obtained by Cohort 6 at age 6. An accelerated longitudinal study that requires 3 years of real time (2008–2010) could thus yield results spanning 6 years of development (ages 6 to 12).

Although developmental psychologists have long discussed the cohort-sequential concept, its applications were limited mainly to identifying cohort and time-of-measurement effects in personality and cognitive tests (e.g., Nesselroade & Baltes, 1974; Schaie, Labouvie, & Buech, 1973).

The need for uniform assessment of multiple birth cohorts over several years might seem to make accelerated longitudinal studies of psychopathology prohibitive. On the other hand, accelerated longitudinal studies can be far more cost-effective than traditional longitudinal studies that require as many years to collect data as the developmental period spanned. But would the magic of predicting from early assessments of psychopathology in one cohort to later assessments in another cohort actually work? The answer depends on the specific assessment procedures, participant samples, and developmental periods spanned. The magic has, in fact, worked very well in accelerated longitudinal studies of psychopathology, as illustrated in the following section.

Accelerated Longitudinal Analyses of Aggressive versus Delinquent Behavior

The nosological category of CD has typically included both aggressive and nonaggressive conduct problems. As an example, the *DSM-IV* criteria for CD include 15 kinds of behavior, such as “aggression to people and animals,” “destruction of property,” “deceitfulness or theft,” and “serious violations of rules” (American Psychiatric Association, 2000, pp. 98–99). Because only three kinds of behavior are required for CD, some children may be diagnosed as having CD solely on the basis of three very aggressive behaviors, whereas others may be diagnosed as having CD solely on the basis of three nonaggressive behaviors.

In contrast to the single diagnostic category provided by *DSM* for different kinds of conduct problems, factor analyses of diverse samples of problem behaviors have typically shown that aggressive and nonaggressive conduct problems tend to load on different factors (e.g., Achenbach, Conners, Quay, Verhulst, & Howell, 1989; Quay, 1993). Aggressive conduct problems may certainly be comorbid with nonaggressive conduct problems in many individuals, just as other kinds of problems may be comorbid. However, because the *DSM*’s nosological model classifies children in the single category of CD whether they manifest only aggressive conduct problems, only nonaggressive conduct problems, or both, it is fair to ask whether the CD category may obscure potentially important differences in patterns of conduct problems.

One way to test for differences between these patterns is to compare their developmental courses. Accelerated longitudinal analyses have been used to do this over ages 4 to 18 years in a randomly selected sample of Dutch children (Stanger, Achenbach, & Verhulst, 1997). The children were assessed with the Child Behavior Checklist (CBCL; Achenbach, 1991b) completed by their parents

five times at 2-year intervals. At each assessment, the parents rated their child on diverse behavioral and emotional problem items. Factor analyses of the problem items produced eight syndromes that included a syndrome designated as *Aggressive Behavior* and one designated as *Delinquent Behavior* (subsequently designated as *Rule-Breaking Behavior*; Achenbach & Rescorla, 2001), which comprised nonaggressive conduct problems such as lying, stealing, running away from home, truancy, and hanging around others who get in trouble.

To compare the developmental courses of the Aggressive and Delinquent syndromes, Stanger et al. (1997) applied an accelerated longitudinal strategy as follows:

- They used CBCL Aggressive and Delinquent syndrome scores for seven birth cohorts of children who were 4, 5, 6, 7, 8, 9, or 10 years old at Time 1. The children were 12, 13, 14, 15, 16, 17, or 18 years old, respectively, at Time 5, which was 8 years later.
- They matched each child in each of the youngest six birth cohorts to a child in the cohort that was 2 years older. (Cohorts differing by 2 years of age were matched to take account of the 2-year intervals between assessments.)
- The matched “partners” were of the same gender and similar SES, and they obtained similar standard scores on the Aggressive and Delinquent syndromes at the two earliest ages at which both members of the pair had been assessed, that is, at Time 1 and Time 2. In other words, Stanger et al. paired children who differed by 2 years of age, who were of the same gender, and who were similar with respect to SES, Aggressive syndrome scores, and Delinquent syndrome scores at two assessment points 2 years apart.
- Separately for the Aggressive and Delinquent syndromes, Stanger et al. then computed Pearson correlations (r) between children’s scores from Time 1 to Time 2, Time 3, Time 4, and Time 5. These r s reflected the stability of the rank ordering of the children’s own scores on a particular syndrome over periods of 2, 4, 6, and 8 years (i.e., the within-cohort stability of scores).
- Stanger et al. also computed analogous r s between the syndrome scores obtained at Time 1 by children in the younger cohorts and the syndrome scores obtained by those children’s matched partners in the 2-years-older cohorts at Times 2, 3, 4, and 5. These r s thus reflected the stability of the rank ordering of scores when r s were computed between one cohort of children at Time 1 and those children’s matched partners in another cohort at

Times 2, 3, 4, and 5 (i.e., the between-cohort stability of scores).

Separately for the Aggressive and Delinquent syndromes, Figure 5.3 displays the mean within-cohort and between-cohort r s obtained over intervals of 2, 4, and 6 years, plus the within-cohort r s over 8 years for the seven cohorts of children. The within-cohort r s extended 2 years beyond the ages that were included in the between-cohort r s.

Figure 5.3 reveals two important findings:

1. Averaged across the seven birth cohorts, the mean between-cohort r s were as large as the within-cohort r s for both the Aggressive syndrome and the Delinquent syndrome over 2-year and 4-year periods and for the Aggressive syndrome over 6-year periods. The only exception was a mean between-cohort r that was only .01 lower than the mean within-cohort r over 6 years for the Delinquent syndrome, a trivial difference that was not statistically significant. Thus, later scores for the Aggressive and Delinquent syndromes were predicted as well from the early scores of children's matched partners from a different cohort as from the children's own early scores. This indicated that accelerated longitudinal analyses worked for the Aggressive and Delinquent syndromes.
2. At all data points for both the within-cohort and between-cohort r s, children's rank orders on the Ag-

gressive syndrome were more stable than on the Delinquent syndrome. The greater stability of Aggressive than Delinquent syndrome scores was shown by within-cohort and between-cohort r s that were .21 higher ($p < .001$ computed by z transformation) for the Aggressive syndrome than for the Delinquent syndrome, averaged over all intervals.

To compare the developmental trajectories for the Aggressive and Delinquent syndromes, Stanger et al. averaged scores obtained by children in each cohort at each age for which the cohort was assessed. Separately for each gender, Figure 5.4 displays the mean Aggressive and Delinquent raw scores at ages 4 to 18 (because the seven cohorts were

Figure 5.4 Mean Aggressive Behavior and Delinquent Behavior syndrome scores averaged across seven birth cohorts of Dutch children, separately for males and females. *Source:* From Stanger et al., 1997, p. 54. "Accelerated Longitudinal Comparison of Aggressive versus Delinquent Syndromes," by C. Stanger, T. M. Achenbach, and F. C. Verhulst, 1997, *Development and Psychopathology*, 9, p. 51. Reprinted with permission of Cambridge University Press.

initially assessed at different ages, data were averaged for pairs of adjoining years, for example, ages 4/5, up to age 18, when data were obtained for only one cohort). Looking at Figure 5.4, you can see that Aggressive syndrome scores declined steadily from ages 4/5 to 18. By contrast, Delinquent syndrome scores showed more complex relations to age, with increases at ages 12/13 for both genders. Girls' Delinquent syndrome scores then declined at age 18, although the data were based on only one cohort at that age.

The Stanger et al. data thus show more linear developmental trends, as well as greater developmental stability in individual differences, for Aggressive syndrome scores than Delinquent syndrome scores. Although Aggressive and Delinquent syndrome scores were significantly associated with each other (r s ranged from .53 at ages 4/5 to .63 at age 18), the findings revealed important differences in the developmental courses of aggressive and nonaggressive conduct problems.

Based on the findings of strong between-cohort predictive relations, predictions could potentially be made from Time 1 scores obtained by one cohort to Time 4 scores obtained by its matched cohort when 8 years older. For example, Time 1 scores obtained at age 4 by the Cohort 4 children could be used to predict Time 4 scores obtained at age 12 by their matched counterparts in Cohort 6. A study spanning 6 years of real time could thus be used to test predictive relations over 8 years of development. Furthermore, tests of predictive relations can be extended to 12 years by matching individuals from successive cohorts to provide predictive correlations between age 4 scores obtained by Cohort 4 members at Time 1 with age 16 scores obtained by Cohort 10 members at Time 4. (To take account of developmental changes in mean scores, the scores need to be standardized within each cohort at each time of assessment.) The potential power of accelerated longitudinal designs greatly increases the attractiveness of short-term longitudinal studies, which are usually far more feasible than long-term studies.

Accelerated longitudinal designs are among the many potential methodological contributions of developmental approaches to psychopathology. They illustrate both the complexity and the promise of developmental perspectives for advancing the study of psychopathology. Cohort and time-of-measurement effects, as well as intraindividual developmental sequences, highlight the need for complex multivariate conceptualizations. The complexity should not deter efforts to cope with the challenges of interrelations between development and psychopathology, however, because powerful research tools are available for coping with such challenges.

Path Designs

Path designs use regression statistics to test predictive pathways between variables assessed at developmentally early points and variables assessed for the same people at developmentally later points. Unlike accelerated longitudinal designs, path designs cannot test relations between variables over developmental periods that are longer than the real-time periods spanned by those developmental periods. However, path designs can test the degree to which multiple variables assessed at different early points in development individually and collectively contribute to the prediction of a particular outcome variable assessed at a later point in development. They can also test the indirect effects of independent variables that predict variables that, in turn, predict the outcome variables of interest.

Various statistical techniques are available for conducting path analyses (Bollen, 1989; Meehl & Waller, 2002). However, without going into the details of the various statistical techniques, we can illustrate some ways in which path designs can contribute to developmental research on the assessment and taxonomy of psychopathology.

Six-Year Predictive Pathways for Aggressive versus Delinquent Behavior

As reported in our illustration of accelerated longitudinal designs, factor analyses have yielded syndromes designated as Aggressive Behavior and Delinquent Behavior (also called Rule-Breaking Behavior). Both within-cohort and between-cohort correlations showed significantly greater developmental stability for scores on the Aggressive syndrome than the Delinquent syndrome among Dutch children (Stanger et al., 1997). Another way to evaluate the developmental course of syndromes is via path designs. This has been done in a national probability sample of American children who were assessed three times over a period of 6 years (Achenbach, Howell, McConaughy, & Stanger, 1995a). Eight empirically based syndromes and numerous family variables were assessed at each of the three points, using methodology similar to that of the Dutch study on which the accelerated longitudinal analyses were based. In addition, at the second and third assessments, information was obtained about potentially important life events that had occurred since the preceding assessment, such as stressful experiences.

Figure 5.5 shows the pathways for Time 1 and Time 2 variables that significantly predicted Time 3 scores on the Aggressive and Delinquent syndromes. The Time 3 syndrome scores were computed by combining parents' ratings

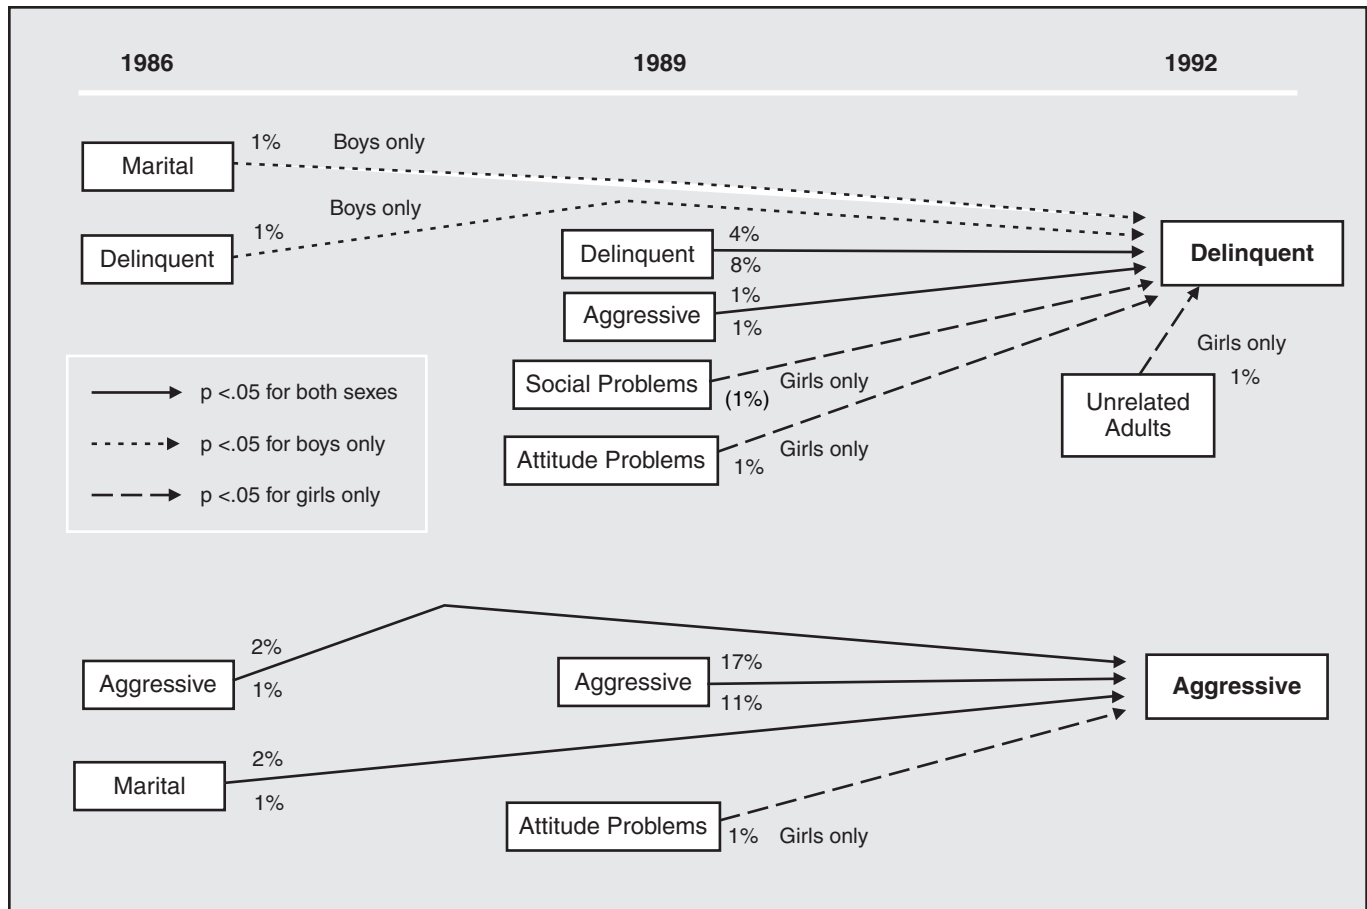

Figure 5.5 Predictive pathways to scores for Aggressive Behavior and Delinquent Behavior syndrome scores in an American national sample. *Source:* From “Six-Year Predictors of Problems in a National Sample of Children and Youth: I. Cross-Informant Syndromes,” by T. M. Achenbach, C. T. Howell, S. H. McConaughy, and C. Stanger, 1995a, *Journal of the American Academy of Child and Adolescent Psychiatry*, 34, p. 343.

on the CBCL, teachers’ ratings on the Teacher’s Report Form (TRF; Achenbach, 1991b), and adolescents’ self-ratings on the Youth Self-Report (YSR; Achenbach, 1991b). The Time 1 syndrome scores were computed from parents’ ratings on the ACQ Behavior Checklist (Achenbach et al., 1991), whereas the Time 2 syndrome scores were computed from parents’ ratings on the CBCL.

The numerals on the predictive paths in Figure 5.5 indicate the effect sizes (ES) in terms of the percentage of variance in the Time 3 syndrome scores that was uniquely accounted for by each of the significant predictors, with the effects of the other predictors partialled out. Each ES for boys is printed above the solid and dotted lines, and each ES for girls is printed below the solid and dashed lines (solid lines = effects that were significant for both genders; dotted lines = effects that were significant only for boys; dashed lines = effects that were significant only for girls). For example, if you look under the Time 2 head-

ing for the Delinquent syndrome in the top portion of Figure 5.5, you can see that the topmost ES was 4% for the prediction of Time 3 Delinquent syndrome scores from Time 2 Delinquent syndrome scores for boys. Beneath the 4% ES for boys, you can see that the corresponding ES for girls was 8%. For both genders, there were also 1% ES for prediction of Time 3 Delinquent syndrome scores from Time 2 Aggressive syndrome scores. For girls only, there were 1% ES for prediction of Time 3 Delinquent scores from Time 2 Social Problems syndrome scores (low Time 2 Social Problems scores predicted high Time 3 Delinquent scores) and Attention Problems syndrome scores. There was an additional 1% ES for the number of unrelated adults living in the girls’ homes between Time 2 and Time 3.

Looking under the Time 1 heading in Figure 5.5, you can see that, for boys, the following two predictors directly accounted for 1% of variance in Time 3 Delinquent scores: the

Time 1 marital status of the boys' parents (Time 3 Delinquent scores were higher if parents were single, separated, or divorced than if they were married or widowed), and the Time 1 Delinquent scores.

In summary, for both genders, more variance in Time 3 Delinquent scores was accounted for by earlier scores on the Delinquent syndrome than by any other variable. However, significant variance was also accounted for by other variables, including scores on the Aggressive, Social Problems, and Attention Problems syndromes, parents' marital status at Time 1, and the number of unrelated adults living in the home between Time 2 and Time 3.

If you look now at the lower portion of Figure 5.5, you can see that Time 2 Aggressive syndrome scores accounted for 17% of the variance in Time 3 Aggressive syndrome scores for boys and 11% for girls. Time 1 Aggressive syndrome scores accounted for an additional 2% of the variance in Time 3 Aggressive syndrome scores for boys and 1% for girls. The only other significant predictors were parents' Time 1 marital status (2% ES for boys; 1% ES for girls) and Time 2 Attention Problems syndrome scores (1% ES for girls only).

By comparing the predictive paths found for Time 3 Delinquent versus Aggressive syndrome scores, you can see that the ES from earlier versions of the same syndrome were smaller for the Delinquent than the Aggressive syndrome: The ES for the Time 1 and Time 2 Delinquent syndromes summed to 5% for boys and 8% for girls, whereas the ES for the Time 1 and Time 2 Aggressive syndrome summed to 19% for boys and 12% for girls. In addition, more numerous other predictors were found for the Delinquent syndrome than the Aggressive syndrome. The other predictors included the Time 2 Aggressive syndrome scores for both genders, Time 2 Social Problems syndrome scores as negative predictors for girls, and the number of unrelated adults in the home between Times 2 and 3 as positive predictors for girls.

Although path designs differ markedly from accelerated longitudinal designs, findings from our examples of these different designs in the Netherlands and the United States suggest the following conclusions about the taxonomic properties of the Aggressive versus Delinquent syndromes:

- Early scores on each syndrome are significant predictors of later scores on the same syndrome, indicating developmental stability in the degree to which individuals manifest each kind of problem.
- The developmental stability of the Aggressive syndrome is greater than the developmental stability of the Delinquent syndrome in terms of the degree to which individ-

uals' rank orders remain consistent over substantial periods of development.

- The course of the Delinquent syndrome in relation to age, gender, and other kinds of problems is more variable than the course of the Aggressive syndrome.
- Overall, the findings suggest that the Aggressive syndrome is more trait-like than the Delinquent syndrome in that individuals maintain more consistent rank orders in relation to peers of the same age and gender, and later Aggressive syndrome scores are predicted more exclusively by scores on the same syndrome than is true for the Delinquent syndrome.

Path Analysis via Structural Equation Modeling

Path analysis can also make use of structural equation modeling (SEM) of hypothesized latent variables that are measured in terms of multiple manifest variables. The researcher specifies a model that includes relations between both the latent and the manifest variables. Mediator variables are often specified as being affected by developmentally early variables but, in turn, as affecting developmentally later variables. As an example, path analyses were used to test predictors of the latent variable of adult aggression from a variety of measures obtained when the adults were children, 15 years earlier (Huesmann, Moise-Titus, Podolski, & Eron, 2003). The latent variable of adult aggression was derived by SEM from 11 manifest variables, including Minnesota Multiphasic Personality Inventory scores, plus self-ratings and informant ratings of various kinds of direct and indirect aggression. Childhood measures of peer-nominated aggression and violent television viewing were found to be significant direct predictors of adult aggression. In addition, as a direct predictor of peer-nominated aggression and violent television viewing, low school achievement was an indirect predictor of adult aggression. Although the results indicated that viewing violent television can increase aggression over long periods, both the preference for viewing violent television and the continuity of aggression from childhood to adulthood may also reflect individual differences in achievement and in the trait-like aspects of aggression indicated by the accelerated longitudinal and path analyses that we described previously.

Growth Curve Designs

Both accelerated longitudinal and path designs examine changes over time in groups based on mean scores for each group. In contrast, growth curve designs permit investigation of changes in individuals as well as changes in groups

over time (Rogosa, Brandt, & Zimowski, 1982). Latent growth curve analysis uses longitudinal data for each individual to model a growth trajectory for that individual. In addition, an average growth trajectory for all individuals is obtained. Each individual growth curve and the group function are described by a set of parameters. For linear functions, these parameters are the intercept and the slope of the line. When growth is not monotonic, quadratic, or cubic, functions may be fit to the data, resulting in parameters for these terms as well. The intercept of the function often represents the initial status of the individual on the dependent measure (i.e., at the first data collection point). The slope represents change in the dependent measure per unit of time over the time period from the first data collection point to the last. The variance estimates for intercept and slope indicate the degree to which individuals in the sample manifest differences in these parameters.

Researchers have developed many statistical procedures to analyze growth in individuals over time. Such procedures include *individual growth curve analysis* (Rogosa et al., 1982), *random effects modeling* (Laird & Ware, 1982), and *hierarchical linear modeling* (HLM; Raudenbush & Bryk, 2002). As HLM is one of the most widely used of these techniques, our summary focuses on this set of procedures.

Hierarchical Linear Modeling Procedures for Examining Growth over Time

HLM is called a hierarchical model because it describes the data in terms of at least two stages or levels. For growth curve analysis, HLM uses Level 1 to specify a within-subject model for each individual in the sample, based on data collected at different points in time. For example, ordinary least squares (OLS) regression could generate a growth trajectory for each person based on that person's score on the CBCL Aggressive syndrome scale at four time points, such as at ages 9, 12, 15, and 18. If the best fit to the data points is a straight line, then Person A's growth over time will be described by Person A's intercept (score at Time 1, or age 9) and A's slope (rate of change in score per year starting at age 9 and ending at age 18). Because no fitted line perfectly captures all data points, each function also contains an error term. In its simplest form, each person's growth over time is represented by Equation 1.

$$\text{Equation 1: } Y_t = a + bX + E$$

where Y_t = The dependent measure of the Aggressive syndrome score at Time "t"

a = Person A's score at age 9 (the initial data point)

X = The number of time units between the initial time point and time "t" (e.g., age 12 = +3)

E represents random error or residual deviation from the predicted score for each individual

In HLM, the Level 2 or between-subjects model predicts the values of each individual's parameters. Thus, the parameters of the Level 1 model are the outcome measures of the Level 2 model. The first step in this analysis is to determine the total amount of variation in the intercept and slope parameters. When individuals have very different initial scores on the dependent measure and they show very different rates of change in the dependent measure over time, then variance in both the intercept and the slope will be high. Variance in the intercept will be minimal when all individuals start at the same point, whereas variance in the slope will be minimal when all individuals decrease (or increase) in the dependent measure at the same rate over time. HLM uses a chi-square procedure to determine if the variances in the intercept and slope are significantly different from zero. If one of these parameters is not significantly different from zero, then the model is constrained or fixed so that individuals are not allowed to have their own values on this parameter in subsequent analyses.

In typical HLM analyses, the first Level 2 model has no predictors. This is called an *unconditional* model, because no additional factors, such as gender, SES, diagnosis, referral status, or life experiences, are used to predict individual growth. In this basic unconditional Level 2 model, the individual parameters from Level 1 (a and b) are predicted only by the "population" mean (derived from the data) and random deviation. The basic unconditional model at Level 2 appears in Equations 2a and 2b:

$$\text{Equation 2a: } a = \beta_{00} + \text{Random deviation}$$

$$\text{Equation 2b: } b = \beta_{10} + \text{Random deviation}$$

Thus, the unconditional model states that the best estimate of an individual's slope or intercept is the population parameter plus some random deviation or error.

At the next stage in the analysis, HLM contrasts this unconditional model with a *conditional* model in which some additional factor is entered as a predictor to explain individual differences in either intercept or slope. For example, one might predict that clinically referred children would have higher Aggressive syndrome scores than non-referred children (reflected in a higher intercept value). One might also predict that children being treated for aggressive behavior problems might show more improvement over time than children receiving no treatment (steeper

negative slope). To test these predictions, the predictor of referral status or “group” is added to the Level 2 model. Because group in this example is a dichotomous variable, it would be coded using a dummy variable such as 0 = Nonreferred and 1 = Referred. Equations 3a and 3b depict the conditional model:

$$\text{Equation 3a: } a = \beta_{00} + \beta_{01}(\text{group}) + \text{Random deviation}$$

$$\text{Equation 3b: } b = \beta_{10} + \beta_{11}(\text{group}) + \text{Random deviation}$$

According to these equations, the individual differences in intercept and slope parameters at Level 1 are determined both by the population values for these parameters and by the child’s status as nonreferred or referred (plus random deviation).

HLM next determines whether the conditional model with predictors is a significant improvement over the unconditional model with no predictors. Essentially, HLM determines the percentage of total variance explained when predictors are added to the model relative to the total variance in the parameters with no predictors. It also tests the significance of each predictor using *t* tests.

Application of Hierarchical Linear Modeling to Developmental Psychopathology

For purposes of explication, we have presented HLM in its simplest form. However, HLM permits analyses that are much more complex. Multiple predictors can be entered at Level 2, and their main effects and interactions can be examined. For example, not only referral status but also gender and SES might be associated with both initial status and change over time in Aggressive syndrome scores. Additionally, some studies might necessitate a 3-level model. For example, a study might compare Aggressive syndrome scores over time in individuals (Level 1) as a function of gender, SES, and referral status (Level 2) in three different countries, such as the United States, the Netherlands, and Korea (Level 3).

Growth curve analysis has become very widely used in developmental research. Because it preserves information about individual trajectories over time and permits examination of multiple predictors of those trajectories, it is very useful for answering major questions in developmental psychopathology. Furthermore, HLM can handle missing data in ways that traditional analysis of variance (ANOVA) and analysis of covariance (ANCOVA) procedures cannot. In a repeated measures ANOVA design, participants who have missing data at one data point may be eliminated from the analysis or may have scores imputed to them. In HLM, however, individuals can remain in the analysis even if they

have some missing data. That is, intercepts and slopes can be calculated for all individuals as long as they have scores for most of the data points (e.g., three out of the four).

Hierarchical Linear Modeling Analyses of Externalizing Problems

Galambos, Barker, and Almeida (2003) used HLM to examine parent and peer influences on the trajectories of externalizing and internalizing problems across five time points from grade 6 to grade 9. Their Time 1 sample consisted of 109 Canadian boys and girls, but attrition reduced the sample to 75 at Time 5. HLM retained all participants in the analysis but gave more weight in the parameter estimation procedure to children with complete data across the five time points.

For illustrative purposes, we will describe Galambos et al.’s (2003) use of HLM to analyze externalizing problems, which were measured by a 24-item self-report questionnaire. At each time point, the children used ratings from 1 (never) to 5 (almost every day) for how many times in the past month they had engaged in behaviors such as disobeying their parents, using drugs, damaging property, or being suspended from school. They also reported on whether they associated with deviant peers. Mothers’ and fathers’ self-reports on a parenting questionnaire at Time 1 were averaged to yield scores for support (warmth), behavioral control (limit setting), and psychological control (disapproval).

When main effects for all measures were analyzed using HLM, associating with deviant peers was the only measure significantly affecting the Time 1 status score (intercept) on externalizing problems. Behavioral control was the only measure significantly associated with the rate of change (slope) in externalizing problems over time. Children whose parents exerted more behavioral control showed smaller increases in externalizing problems over time than their peers.

In the second model, all four main effects plus the interactions between deviant peers and the three parenting measures were analyzed using HLM. The same two main effects were significant (deviant peers for the intercept and behavioral control for the slope). The interaction between deviant peers and behavioral control also had a significant effect on the slope of externalizing problems. Follow-up analyses tested slopes in the four groups produced by a median split on both deviant peers and behavioral control. Only the group who scored above the median on deviant peers and above the median on behavioral control had a slower increase in externalizing problems over time. As the authors concluded, children who had more deviant peers

had higher externalizing problems scores at Time 1, and there was a general trend for all children to increase in externalizing problems over time. However, only children whose parents exerted more behavioral control in the face of greater association with deviant peers showed reduced increases in externalizing problems over time. When additional HLM analyses included gender as a covariate, the same basic results were obtained. Interestingly, boys demonstrated higher Time 1 scores (higher intercept) than girls, but girls showed faster increases (higher slope) in externalizing problems from grades 6 to 9 than boys.

LIFE SPAN APPLICATIONS

To apply developmental approaches to psychopathology across the life span, we should consider lessons learned from research on children. Changes in the prevalence, patterning, and possibilities for assessing problems do not end at maturity. Although the changes may be slower and less conspicuously associated with biological development than during childhood, adult psychopathology may be no more independent of developmental changes than is child psychopathology. However, to test the developmental course of psychopathology, its correlates, and its outcomes, we need assessment procedures and taxonomic constructs that can take account of both the changes and the continuities in psychopathology from childhood to adulthood and old age. Furthermore, it would be desirable to quantify adult assessment and taxonomy in ways that lend themselves to powerful developmental research designs, such as accelerated longitudinal, path, and growth curve designs.

The value of measures that can track continuities and changes over significant periods of adulthood has been demonstrated in studies of cognitive functioning. As an example, latent growth models were applied to 11 cognitive measures for 550 Swedish adults who were initially tested at age 44 to 88 and were then retested at intervals of 3 and 6 years thereafter (Finkel, Reynolds, McArdle, Gatz, & Pedersen, 2003). The results revealed different trajectories for different kinds of abilities, including stability into old age for crystallized ability, linear declines in other abilities, and significant acceleration in linear declines after age 65 for measures that depended on speed. Significant individual variations in growth curves were found for some of the measures.

Similar growth curve analyses can be applied to scores measuring psychopathology in adults, such as those derived from the Achenbach System of Empirically Based Assessment (ASEBA) forms for adults: the Adult Self-

Report and Adult Behavior Checklist for Ages 18 to 59 and the Older Adult Self-Report and Older Adult Behavior Checklist for Ages 60 to 90+ (Achenbach et al., 2004; Achenbach & Rescorla, 2003). Some problem scales are common to both adult age groups. Examples include the empirically based Anxious/Depressed, Somatic Complaints, and Thought Problems syndrome scales and the DSM-oriented Depressive Problems, Anxiety Problems, Somatic Problems, and Antisocial Personality Problems scales. One syndrome scale, named Intrusive, is specific to ages 18 to 59. Other scales are specific to ages 60 to 90+, such as the Irritable/Disinhibited, Memory/Cognition Problems, Worries, and Functional Impairment syndrome scales. Some syndrome scales for ages 18 to 59 have counterpart scales on the CBCL, TRF, and YSR, which are the ASEBA forms for ages 6 to 18. These syndrome scales include Attention Problems, Aggressive Behavior, and Rule-Breaking Behavior.

Longitudinal research has shown that high problem scores on the adult Intrusive syndrome, as well as on the adult Aggressive Behavior syndrome, are strongly predicted by high scores on the child/adolescent Aggressive syndrome (Achenbach, Howell, McConaughy, & Stanger, 1995c). These findings indicate that some aggressive children and adolescents are socially intrusive as adults, whereas others remain more overtly aggressive. The same research shows that high child and adolescent scores on the Attention Problems syndrome predict high scores on the adult version of this syndrome. However, the adult version is characterized less by overactivity and more by irresponsibility than the child/adolescent version.

Because parallel self-report and other-report forms are available for ages 11 to 90+, developmental analyses of adult psychopathology can be compared for self-reports, reports by others, and aggregations of multisource data. In addition, because many of the empirically based and nosologically based scales for adults and older adults are similar to those for children and adolescents, ASEBA forms are well suited to both long-term longitudinal studies and to multigeneration family studies. Multigeneration family studies are particularly useful in behavior genetics research designed to identify genetic effects, environmental effects, and their interactions in parents and their children.

MULTICULTURAL APPLICATIONS

To avoid incorrectly assuming that findings in a single culture reflect universals, it is important to apply the same

standardized assessment procedures for psychopathology to people from a variety of cultures. If the assessment procedures are found to function similarly in different cultures, they offer the potential for testing the course and correlates of psychopathology across the different cultures. Findings that are similar in different cultures can be assumed to have greater generality than findings that are obtained in only a single culture. An additional advantage of assessment procedures that function similarly in different cultures is that they foster multicultural collaborations, which can greatly extend the reach of developmental research on psychopathology.

Multicultural Consistencies and Differences

As an example of multicultural research, Crijnen, Achenbach, and Verhulst (1997, 1999) and Verhulst et al. (2003) compared the performance of empirically based instruments completed by parents of representative samples of children in 12 cultures and self-report instruments completed by representative samples of youths in 7 cultures, respectively. The cultures were Australia, Belgium, China, Germany, Greece, Israel, Jamaica, the Netherlands, Puerto Rico, Sweden, Thailand, Turkey, and the United States. Completion rates in all cultures were at least 80% for parents' reports and at least 78% for youths' self-reports. The mean total problems scores were quite similar across most cultures, as were gender differences in problem scores. Youths reported more problems than parents in all cultures. Using the approach pioneered by Crijnen et al. and Verhulst et al., we have since analyzed data for more than 60,000 children assessed in 30 cultures to obtain a more extensive picture of the similarities and differences between reported problems (Achenbach & Rescorla, 2006; Rescorla et al., 2005).

Although these multicultural studies indicated some notable cross-cultural differences in scores for certain syndromes, Pearson r s between mean problem item scores for every combination of cultures were large, according to Cohen's (1988) criteria. (Pearson r s were computed by first obtaining the mean score for each problem item within each culture and then computing the r between the mean scores on all the items for Culture A versus Culture B, and then Culture A versus Culture C, and so on for all pairs of cultures.) The mean of the cross-cultural correlations ranged from .74 to .78 among all pairings of the cultures for which parents' ratings were analyzed, .74 among all the cultures for which teachers' ratings were analyzed, and .75 among all pairings of the cultures for which youths' self-ratings

were analyzed. These substantial r s indicated that the same problems tended to receive relatively high, medium, or low scores across the cultures. For cultures from which cross-informant r s were available (e.g., r s between parent and teacher ratings), no culture's cross-informant r differed significantly from the mean of the r s for the available cultures (Verhulst & Achenbach, 1995). These findings indicate that the empirically based instruments performed similarly in diverse cultures.

Another aspect of multicultural research involves demonstrating whether the same syndromes of problems are found in different cultures. The 8-syndrome model derived from U.S. CBCL, TRF, and YSR data has been tested against data from many other cultures. In one study, the U.S. syndromes were closely replicated in data from the Netherlands (deGroot, Koot, & Verhulst, 1994). In another study, confirmatory factor analysis (CFA) of the eight CBCL syndromes in data from a large Turkish sample indicated excellent fit (Dumenci, Erol, Achenbach, & Simsek, 2004). When applying CFA to data from 30 very diverse cultures, Ivanova et al. (2005) found that the configural invariance of the 8-syndrome model was well supported in all cultures.

In the Netherlands and the United States, the empirically based instruments have been used in parallel longitudinal studies of large, representative samples of children and adolescents. Predictive correlations from initial scores on empirically based syndromes to subsequent scores and to various signs of disturbance over 6 years were very similar in the Dutch and American samples (Achenbach, Howell, McConaughy, & Stanger, 1995a, 1995b, 1995c, 1998; Verhulst & van der Ende, 1992a, 1992b). Furthermore, a 14-year follow-up of the Dutch sample showed that adult *DSM* diagnoses and signs of disturbance were significantly predicted by initial scores on the empirically based instruments (Hofstra, van der Ende, & Verhulst, 2001, 2002a, 2002b). The multicultural comparisons of empirically based instruments thus show that they can be used in similar ways across diverse cultures with fairly similar results.

Direct comparisons have been made for a few adult disorders in representative samples assessed in different cultures with the same nosologically based instruments. For example, Helzer et al. (1990) reported age-standardized lifetime prevalence rates of alcohol abuse and dependence for epidemiological samples from St. Louis, Edmonton, Puerto Rico, Taiwan, and Korea. Completion rates ranged from 67% in Taiwan to 91% in Puerto Rico. Although no direct statistical comparisons were made between cultures, some differences were quite large, with alcohol dependence

ranging from 2.9% of metropolitan Taiwanese men to 20.4% of Korean men. For participants who were diagnosed as having alcohol dependence, there was considerable similarity in the rank ordering of the frequency of the criterial symptoms, with Spearman correlations ranging from .66 between Edmonton and Korea to .94 between St. Louis and both Edmonton and Korea.

Prevalence rates for more diverse diagnostic categories have been reported in a study of 14 countries (WHO World Mental Health Survey Consortium, 2004). Although versions of the Composite International Diagnostic Interview (CIDI) were used in all countries, disorders thought to have “low relevance” (p. 2587) were omitted in some countries, and difficulties in implementing the initial surveys resulted in large amounts of missing data in some countries. In addition, completion rates were under 80% for 13 of the 14 countries, with the completion rate being only 45.9% in France and from 50.6% to 57.8% in four other countries. The variations in the CIDI and the modest completion rates may have contributed to the great variation found for prevalence rates, which ranged from 4.3% in Shanghai to 26.4% in the United States for any disorder identified by the CIDI. When tabulated within the broad categories of anxiety, mood, impulse control, and substance use/dependence disorder, the prevalence rates also showed great variation among the 14 countries. For example, the prevalence rates for mood disorders ranged from 2.4% in Shanghai to 18.2% in the United States.

Although we found no studies that directly compared prevalence rates of DISC-based *DSM* diagnoses of child disorders in different cultures, studies using similar versions of the DISC with general population samples in single cultures have reported substantial differences in prevalence rates for *DSM-III-R* diagnoses (Breton et al., 1999; Shaffer et al., 1996; Steinhausen, Metzke, Meier, & Kannenberg, 1997, 1998; Verhulst et al., 1997). These studies all made *DSM-III-R* diagnoses from the DISC, but methodological differences in the ways they obtained and combined data from parent and self-reports and in their yes/no decision rules for making diagnoses may have contributed more to the apparent differences in prevalence rates than did cultural factors. As detailed by Achenbach and Rescorla (2006), nosological research on cross-cultural consistencies and differences requires operationalizing nosological constructs via assessment procedures that uniformly and effectively take account of informant variations in large representative samples drawn from different cultures.

ADVANCING ASSESSMENT, TAXONOMY, AND DIAGNOSIS

To set the stage for considering how assessment, taxonomy, and diagnosis can be advanced, Figure 5.6 illustrates the dynamic and continuous relations between them.

To be accurate, diagnosis requires ways of conceptualizing the phenomena that are to be diagnosed. Taxonomies provide structures for conceptualizing psychopathology in terms of similarities and differences that can then provide targets for diagnosis. Taxonomic structures for behavioral and emotional problems are commonly conceptualized in terms of syndromes. The value of particular syndromes depends on the degree to which they are found to have important correlates, such as differences in etiology, prognosis without intervention, responsiveness to particular interventions, and long-term developmental pathways. To develop reliable, valid, and useful taxonomies, we need reliable and valid assessment of diverse samples of people. After a taxonomy has been derived from assessment data, the taxonomy can be used to guide assessment of new cases to determine which taxa the cases resemble.

In Figure 5.6, “diagnosis” includes *diagnostic processes*, *formal diagnoses*, and *diagnostic formulations*. To avoid confusion about diagnosis, it is important to keep in mind these three different aspects of diagnosis. Assessment and taxonomy are important contributors to all three. Diagnostic

Figure 5.6 Relations between assessment, taxonomy, and diagnosis. As explained in text, “diagnosis” includes *diagnostic processes* (gathering data), *formal diagnoses* (classifying cases and disorders), and *diagnostic formulations* (integrating all relevant data for each case). Copyright by T. M. Achenbach. Reproduced by permission.

processes clearly include assessment operations that should be guided by a taxonomy of syndromes. Formal diagnoses involve identification of the taxa that are most relevant to each case. And diagnostic formulations integrate information specific to the case with the type of information on which taxonomic decisions and formal diagnoses are based.

Challenges to Be Met

DSM-III (American Psychiatric Association, 1980) was an important milestone in advancing the nosological approach toward more explicit and testable criteria for psychopathology. Since 1980, *DSM-III* and its successors have generated a tremendous amount of research, as well as major changes in clinical training and practice. An especially important research goal has been to improve the diagnosis of *DSM*-defined disorders via structured interviews. Accordingly, enormous resources have been invested in revising and testing structured interviews as ways of operationalizing the *DSM-III*, *DSM-III-R*, and *DSM-IV* criteria for childhood disorders (e.g., Costello et al., 1984; Lahey et al., 1996; Shaffer et al., 1996). Substantial resources have also been invested in operationalizing *DSM* criteria for adult disorders via structured interviews (e.g., Regier et al., 1998).

Efforts to diagnose *DSM*-defined disorders via structured interviews have molded research, training, and practice according to the *DSM*'s diagnostic model, which requires yes-or-no decisions about each criterial feature of each diagnostic category. Diagnostic interviews, such as the DISC for children and DIS for adults, are viewed as quasi gold standards for assessing psychopathology. However, studies of structured diagnostic interviews have revealed certain challenges to assessment, taxonomy, and diagnosis of psychopathology. We first summarize these challenges at the level of specific methodological issues. We then consider possibilities for advancing assessment, taxonomy, and diagnosis to improve understanding, prevention, and treatment of psychopathology.

Challenges Revealed by Studies of Structured Diagnostic Interviews

The challenges can be summarized as follows:

1. *Test-retest attenuation*: Fewer symptoms are typically reported at second interviews than at initial interviews, causing declines in the number of diagnoses over even very short periods such as a week (e.g., Edelbrock, Costello, Dulcan, Kalas, & Conover, 1985; Helzer, Spitznagel, & McEvoy, 1987; P. Jensen et al., 1995; R. E. Roberts, Solovitz, Chen, & Casat, 1996).

2. *Low to moderate cross-informant agreement*: People report different symptoms about themselves than others report for them, causing disagreements between diagnoses based on self-reports versus informant reports (e.g., Achenbach et al., 1987, 2005; Klonsky et al., 2002; Meyer, 2002; Meyer et al., 2001).
3. *Diagnoses made from structured interviews show mediocre agreement with clinical diagnoses*: Even when designed to operationalize the *DSM* criteria, structured interviews such as the DISC and DIS often produce different *DSM* diagnoses than do clinical assessments (e.g., Costello et al., 1984; Eaton et al., 2000; A. L. Jensen & Weisz, 2002; Lewczyk et al., 2003; Rettew et al., 2005).
4. *High rates of comorbidity*: Rates of comorbidity between some diagnoses are so high as to raise questions about whether the diagnoses actually represent different disorders (e.g., Faraone et al., 1991; Walker et al., 1991; Wilens et al., 2002).
5. *Great variations in prevalence rates of DSM diagnoses made from structured interviews in epidemiological surveys*: Despite operationalization of *DSM* criteria via structured interviews, prevalence rates show much greater variation than would be expected from sampling differences (e.g., Achenbach & Rescorla, 2006; Breton et al., 1999; Shaffer et al., 1996; Verhulst et al., 1997).

The challenges raised by studies of structured diagnostic interviews expose fundamental problems that cut across assessment, taxonomy, and diagnosis. These problems need to be addressed in efforts to improve understanding, prevention, and treatment of psychopathology. Some of the problems revealed by studies of structured interviews may characterize other assessment procedures as well. For example, test-retest attenuation, low to moderate cross-informant agreement, and high rates of covariation (i.e., comorbidity) among different kinds of problems are found in most procedures for obtaining information about people's problems (e.g., Achenbach & Rescorla, 2001, 2003; Krueger, 2002; Krueger & Piasecki, 2002). Agreement between most assessment procedures and *DSM* clinical diagnoses also tends to be low, although this may be most troubling for procedures that are explicitly designed to correspond to *DSM* diagnoses (e.g., DuPaul, Power, Anastopoulos, & Reid, 1998; Gadow et al., 2002). If assessment procedures are not specifically designed to correspond to *DSM* diagnoses, their modest agreement with *DSM* clinical diagnoses is less surprising than if they are designed to correspond to *DSM* diagnoses.

Although some of the challenges faced by structured interviews are quite general, the problems are exacerbated by the *DSM* requirement to make diagnoses according to fixed rules for the criteria that must be met. For example, a decline in the number of symptoms endorsed from one occasion to another may reflect the general phenomenon of test-retest attenuation. However, according to *DSM*'s fixed rules for the number of symptoms required for each diagnosis, a reduction of even one symptom can change diagnostic decisions from yes to no for *DSM* diagnoses. Similarly, disagreements between informants' reports of even a single symptom can cause major differences in diagnoses made on the basis of self-reports versus reports by various other informants. In addition, the great sensitivity of *DSM* diagnoses to the precise definition, number, duration, and co-occurrence of reported symptoms may contribute to the great variations in prevalence rates found in different epidemiological studies. For example, R. E. Roberts, Attkisson, and Rosenblatt (1998) found prevalence rates ranging from 1% to 50% among epidemiological studies of diagnoses of child and adolescent disorders. Assessment procedures that have uniformly operationalized a particular set of taxonomic constructs have yielded more consistent epidemiological findings than structured interviews that have attempted to operationalize *DSM* diagnostic criteria but that have varied considerably in how they obtained judgments of whether each criterion was met (e.g., Crijnen et al., 1997, 1999; Rescorla et al., 2005; Verhulst et al., 2003).

Other Types of Challenges

Assessment, taxonomy, and diagnosis also face challenges raised by the need to identify and combine optimal sources and kinds of assessment data for taxonomy and diagnosis; the need to take account of variations related to age, gen-

der, and sources of data; and the need to distinguish between cultural differences and individual differences. Table 5.1 summarizes these challenges. Progress in meeting the various challenges requires systematic research that can bridge the gaps between nosological and empirically based approaches to provide assessment procedures, taxonomic constructs, and diagnostic targets that can be used by both approaches.

QUANTITATIVE AIDS TO MEETING THE CHALLENGES

DSM-III, *DSM-III-R*, and *DSM-IV* have brought significant advances in making diagnostic criteria more explicit. However, the *DSM*'s diagnostic criteria and categories are based on the assumption that each diagnostic category represents a separate disorder. This assumption is indeed tenable for disorders for which specific pathogens or other physical abnormalities have been identified. For example, diagnostic categories for infectious diseases such as tuberculosis, diphtheria, and AIDS can be confidently defined in terms of pathogens that are necessary (though not always sufficient) for the disorder to occur. Diagnostic categories for cancer can be defined in terms of specific kinds and locations of tissue pathology, even if specific pathogens have not been identified.

Some forms of psychopathology may eventually be found to involve physical pathogens and/or other physical abnormalities. However, until physical abnormalities are validated, it may be premature to require yes/no decisions for diagnoses of behavioral and emotional problems. Because even physical abnormalities may not all be identifiable in terms of yes/no dichotomies, the search for physical abnormalities may also be more productive if diagnostic criteria and categories are quantified. Even if the current *DSM-IV* diagnostic categories are to be retained in *DSM-V*, they could benefit from quantification by allowing each criterion feature to be scored quantitatively and by aggregating the scored features into a total score for each diagnosis.

If retention of the categorical diagnostic format is desired, cut points can nevertheless be established on distributions of quantitative scores. Rather than being established a priori by committees of experts, the cut points can be based on scores that discriminate efficiently between representative samples of people who are judged to be relatively normal (i.e., "healthy" samples) versus people who are judged to need mental health services. To take account of age, gender, and informant differences, cut points can be established on the basis of separate distributions obtained for people of

TABLE 5.1 Challenges to Be Met for Advancing Assessment, Taxonomy, and Diagnosis

1. <i>Test-retest attenuation</i> : The decline in problems reported from initial interviews to subsequent interviews.
2. <i>Low to moderate cross-informant agreement</i> : Different informants tend to report different problems.
3. <i>Limited agreement between diagnoses made from structured interviews and clinical diagnoses</i> .
4. <i>High rates of comorbidity</i> : Comorbidity between some diagnoses is so high as to raise questions about whether the diagnoses represent different disorders.
5. <i>Great variations in prevalence rates of DSM diagnoses made from structured interviews in epidemiological surveys</i> .
6. <i>The need to integrate multisource data</i> .
7. <i>The need to take account of differences related to age, gender, and sources of data</i> .
8. <i>The need to distinguish individual differences from cultural differences</i> .

each gender within particular age ranges, according to assessment data obtained from different kinds of informants. To avoid transferring the disadvantages of purely categorical diagnoses to diagnoses based on scores, the cut points should be based on findings of variations related to age, gender, and type of informant. In addition, levels of deviance can be identified to distinguish between people who have extreme degrees of the problems encompassed by a diagnostic category versus people who have less extreme degrees of the problems versus people who are in the normal range. Even if cut points are imposed on distributions of scores, the continuous scores should be retained to provide more precise measures of problems than are provided by categorization. Quantitative diagnostic scores also have advantages for measuring change over time, such as by comparing scores before, during, and after treatment and by comparing scores at different points in development.

Advantages of Quantification for Research

Quantification of the criterial features of diagnostic categories and of the diagnostic categories themselves offers a variety of advantages for most kinds of research on psychopathology.

Preserving Information

One advantage is that quantification of features typically preserves more information about the features than yes/no categorization does. This is especially true when neither the boundaries of each feature nor of the diagnostic categories are well validated. In such cases, imposition of unvalidated boundaries and categorical assessment procedures may cause cases to be misclassified. Even if certain disorders are ultimately found to have categorical boundaries, the inevitability of measurement error will prevent assessment procedures from infallibly distinguishing between individuals whose problems fall within those boundaries and individuals whose problems are not entirely congruent with the categorical boundaries.

Avoiding Forced Choices

Quantified assessment procedures avoid forced choices because they capture the degree to which individuals' problems approximate particular diagnostic categories and because quantification can take account of measurement error. By indicating the degree to which individuals' problems resemble each relevant diagnostic category, quantified assessment can help to prevent the premature closure risked by placing individuals in diagnostic categories that may be wrong.

Increasing Precision

A further advantage of quantification is that it can improve research by increasing the precision of data obtained about each characteristic of each individual. It can also improve research by making possible the use of more varied and powerful analytic tools than are available for categorical data. These analytic tools are especially useful for the following research areas that are increasingly important for advancing assessment, taxonomy, and diagnosis: identification of patterns of psychopathology and their correlates; life span developmental analyses of adaptive and maladaptive functioning; behavior genetics; epidemiology; efficacy, effectiveness, and outcomes of different kinds of interventions; pharmacokinetics of medications; biochemical correlates of behavioral and emotional problems; and multicultural applications.

Advantages of Quantification for Conceptualizing Psychopathology

In addition to the advantages it offers for research, quantification can also improve our ways of thinking about psychopathology, as outlined in the following sections.

Quantitative Aspects of Prototypes

In earlier sections, we outlined prototypes as models for taxonomy. Insofar as people mentally represent categories in terms of prototypes (sets of correlated features), people's representations of even categorical taxonomic constructs involve quantification. That is, a prototype for a category encompasses multiple features that are not perfectly correlated with each other. On the other hand, individuals who manifest many features of a prototype are more easily assigned to the category represented by that prototype than individuals who manifest fewer features of the prototype. Individuals who manifest multiple features of more than one prototype may be especially hard to classify by a single category. If such individuals have enough problems to need mental health services, then their problems can be described in terms of scores on multiple prototypes. According to *DSM's* rules, individuals who manifest enough prototypical features of two categories to qualify for both categories are assumed to have the disorders represented by both categories; that is, they have comorbid disorders. (Although *DSM* has some preemptive rules, such as CD taking precedence over ODD when criteria for both disorders are met, these rules are often suspended in research and practice.)

If diagnostic categories are quantified in terms of the number of their prototypical features, the categories

would correspond more closely to people's mental representations in terms of prototypes. In other words, because people use the number of features corresponding to their mental prototypes as a basis for classifying individuals and because the reliability and confidence with which individuals are classified depend on the number of prototypical features manifested, diagnostic categories may be used more effectively if they take advantage of the quantification that is inherent in mental classification processes. Because psychopathology often includes features of multiple diagnostic categories, quantification of each category would allow users of the categories to think about borderline cases and comorbidity explicitly in terms of the scores obtained for each diagnostic category. Borderline cases, for example, could be operationally defined in terms of scores that are high enough to be somewhat above the normal range but not so high as to be clearly clinically deviant. Furthermore, manifestations of features of multiple categories could be explicitly documented in terms of profiles of scores for all the relevant categories without implying that each elevated score indicated a separate (or comorbid) disorder.

Conceptualizing Cross-Informant Variations

Quantification of diagnostic categories can also facilitate conceptualization of cross-informant variations in assessment data. By allowing for variations in the degree to which particular problems are manifested, quantified taxonomic categories can help us use both the differences and the similarities in reports by different sources for determining the overall level of individuals' problems and how consistently they are manifested. For example, if all sources report high levels of hyperactivity for a child, this would provide consistent evidence for a disorder that involves hyperactivity, such as the Hyperactive-Impulsive type of ADHD. On the other hand, suppose that hyperactivity is reported by certain informants but not others. A purely categorical system forces us to choose among different informants' reports to make a yes/no decision about whether the individual is hyperactive. However, quantified categories enable us to integrate scores obtained from the different informants into the scores for each relevant category. This can be done by averaging scores, using weighted means of scores, matching profile patterns from different informants to profile types, and matching scores from different informants to latent classes or latent profiles.

In summary, the quantitative aspects of mental prototypes provide a natural basis for conceptualizing psycho-

pathology in terms of quantified categories. Quantified categories can mitigate difficulties in making diagnostic decisions about individuals who need help but whose problems are too diverse to meet criteria for a single diagnostic category, as well as individuals who meet criteria for multiple diagnostic categories. Quantified categories also facilitate thinking about individuals who have significant problems that correspond to a particular diagnostic category but that do not quite reach the threshold required for a categorical diagnosis. In addition, when different sources report different problems for an individual, profiles of quantified categories scored from each source can be used to document similarities and differences in how the individual is perceived.

Advantages of Quantification for Mental Health Services

For mental health services, a fundamental advantage of quantification is that decisions about who needs services and what kind of services they need can be based on consideration of clients' profiles of adaptive and maladaptive functioning rather than on whether they meet categorical criteria for a particular diagnostic category. Excessive reliance on diagnostic categories as a basis for treatment decisions may exclude clients who need help but do not fit the categories. On the other hand, if clients meet criteria for a diagnostic category, then it may be too readily assumed that they are deviant even if they are adapting well. Furthermore, excessive reliance on diagnostic categories may cause treatment to focus more narrowly on the categories than is warranted either by the client's needs or by the ability of categorically based treatments to ameliorate broad spectra of problems. This may be especially true when a mental health service specializes in a particular diagnostic category such as depression, anxiety, or ADHD. Because the diagnostic procedures, treatment modalities, and clinicians in such services tend to focus on the target category, clients and their problems may be viewed primarily in terms of that category. Assessment of multiple quantified categories can reveal the degree to which individuals' problems really are or are not concentrated in a particular diagnostic category.

EFFORTS TO QUANTIFY DIAGNOSTIC CATEGORIES

The following sections outline some efforts to confer the benefits of quantification on *DSM* diagnostic categories.

Rating Scales for Diagnostic and Statistical Manual Categories

One approach to quantifying diagnostic categories has been to reproduce the symptom criteria for individual *DSM* categories in rating scale formats.

ADHD Rating Scale IV

DuPaul et al. (1998) constructed the ADHD Rating Scale IV, which consists of the *DSM-IV* symptom criteria for the Inattentive and Hyperactive-Impulsive types of ADHD. Parents and teachers rate each symptom as 0 = never or rarely, 1 = sometimes, 2 = often, or 3 = very often. The symptom scores are then summed to provide scale scores for Inattention, Hyperactivity-Impulsivity, and Total ADHD. DuPaul et al. reported that categorical diagnoses of ADHD correlated between .08 and .44 with scores on the scales of the ADHD Rating Scale IV completed by parents and teachers. However, the authors also reported correlations of .76 to .88 between teachers' ratings on the ADHD Rating Scale IV and the corresponding quantitative scales of the Conners Teacher Rating Scale 39 (C-TRS; Conners, 1997).

Youth's Inventory 4

In an effort to quantify a broader range of *DSM* diagnostic categories, Gadow and Sprafkin (1998, 1999) developed rating scales consisting of symptoms from multiple *DSM-IV* categories. As an example, the Youth's Inventory 4 (YI-4; Gadow & Sprafkin, 1999) is a self-rating form consisting of *DSM-IV* symptoms that youths are to rate 0, 1, 2, or 3 according to gradations like those of the ADHD Rating Scale IV. Symptom severity scores are obtained by summing the numerical ratings on each scale. Versions of a companion rating form, the Adolescent Symptom Inventory 4 (ASI-4; Gadow & Sprafkin, 1998), are designed to obtain parent and teacher ratings of many of the same *DSM* symptoms.

Using a sample of 11- to 18-year-olds whose parents requested an outpatient evaluation at a university clinic, Gadow et al. (2002) tested associations between symptom severity scores on the *DSM* scales of the YI-4 and *DSM* diagnoses in the youths' clinic charts. Gadow et al. bundled diagnoses into the following five groups: ADHD, ODD, CD, depressive disorders, and anxiety disorders. Because most youths received more than one *DSM* diagnosis, many youths were included in multiple diagnostic groups. Gadow et al. then identified the YI-4 *DSM* scales whose symptom severity scores had the highest point-biserial *rs* with the diagnoses. The highest *rs* ranged from .06 for the YI-4 ODD scale with *DSM* diagnoses of ODD to .38 for the Major Depressive Disorder scale with *DSM* diagnoses of

depressive disorders, with mean $r = .25$ (computed by Fisher's z transformation).

Although the authors did not report associations between diagnoses and parent or teacher ratings, the Pearson *rs* between the YI-4 and parents' ASI-4 ratings on corresponding *DSM* scales ranged from .05 to .50. All correlations between the YI-4 and teachers' ASI-4 ratings on the corresponding *DSM* scales were extremely low ($r < .18$). However, the YI-4 scales yielded many *rs* in the .60s and .70s with the youths' self-ratings on non*DSM*-based scales scored quantitatively from the Children's Depression Inventory (Kovacs, 1992), the Multidimensional Anxiety Scale for Children (March, 1997), and the YSR (Achenbach, 1991b). Thus, although YI-4 *DSM* symptom severity scores did not yield much agreement with *DSM* clinical diagnoses nor with parent or teacher ratings, self-ratings on the YI-4 *DSM* symptom scales were strongly associated with self-ratings on other quantitative measures of problems.

Findings for the ADHD Rating Scale IV and the YI-4 thus suggest that parent, teacher, and self-ratings of actual *DSM* symptom items do not necessarily agree well with *DSM* diagnoses that are based on the same items. The impediments to agreement between the *DSM* scales and *DSM* diagnoses might include the diagnosticians' use of multiple sources of data, plus their use of additional criteria such as the duration of symptoms.

DSM-Oriented Scales

Another approach to quantifying *DSM* diagnostic categories is to start with items that are of proven value for obtaining ratings by the relevant informants and then selecting those items that are very consistent with *DSM* diagnostic categories, whether or not the items have exact counterparts among the *DSM* symptom items. Because each *DSM* diagnostic category in effect represents a diagnostic construct, experts' understanding of the diagnostic constructs may provide a good basis for selecting items that are appropriately rated by informants but that may not be literally the same as the *DSM* symptom criteria. However, because experts' judgments may vary with such characteristics as their professional training, the settings in which they work, the types of clients they see, and their cultural backgrounds, it is important to identify items on which judgments by diverse experts converge.

To make use of judgments by experts who varied greatly with respect to their training, work settings, clients, and cultures, Achenbach, Dumenci, and Rescorla (2001) invited 22 psychiatrists and psychologists from 16 cultures around the world to rate problem items for their consistency with

DSM diagnostic categories for child and adolescent disorders. The experts had all published on psychopathology and had a mean of 19.1 years of experience since their first doctorate. Five had both MD and PhD degrees. The experts were given the *DSM* criteria for nine categories of disorders that are defined largely in terms of behavioral and emotional problems. They then rated each problem item as 0 = not consistent, 1 = somewhat consistent, or 2 = very consistent with each *DSM* category. Because the objective was to obtain the experts' judgments of the diagnostic constructs represented by the *DSM* categories, they could rate problem items as being very consistent with a category even if the items did not have precise counterparts among the *DSM* symptom criteria.

Items that were rated as very consistent with a *DSM* category by a substantial majority of the experts (at least 64%) were assigned to a scale for that category. The scales are designated as "*DSM*-oriented" because they capture what is common to diverse experts' understanding of the diagnostic constructs underlying *DSM* categories, rather than being verbatim statements of the *DSM* criteria. Enough items met criteria to form *DSM*-oriented scales that were designated as follows: Affective Problems (including Dysthymia and Major Depression); Anxiety Problems (including Generalized Anxiety Disorder, Separation Anxiety Disorder, and Specific Phobia); Somatic Problems (including Somatization and Somatoform Disorders); ADHD Problems (including Hyperactive-Impulsive and Inattentive types); Oppositional Defiant Problems; and Conduct Problems.

To enable users to judge the degree of deviance indicated by scores on the *DSM*-oriented scales, normative data were obtained for a national probability sample of 6- to 18-year-olds who had not received mental health services in the preceding 12 months (i.e., a "healthy sample" in epidemiological terms). Scores on the *DSM*-oriented scales are displayed on profiles in relation to norms for each gender according to particular age ranges, separately for parent ratings on the CBCL, teacher ratings on the TRF, and self-ratings on the YSR (Achenbach & Rescorla, 2001).

Relations to Diagnostic and Statistical Manual Diagnoses

Point-biserial *rs* have been reported between *DSM-IV* clinical diagnoses and the *DSM*-oriented scales in a university outpatient clinic sample (Achenbach & Rescorla, 2001, p. 130). Like the diagnoses reported by Gadow et al. (2002) for youths who completed the YI-4, the diagnoses were obtained from clinical records and were based on multiple sources of data. However, unlike the ages 11 to 18 spanned by the Gadow et al. data for self-ratings on the YI-4, the

data for the *DSM*-oriented scales spanned ages 6 to 18 and were obtained from parents' ratings on the CBCL/6–18. For the same groupings of diagnoses as were reported by Gadow et al., the correlations between *DSM* clinical diagnoses and the corresponding *DSM*-oriented scales ranged from .34 for CD to .60 for ADHD, with mean $r = .45$ (computed by Fisher's z transformation).

As another way of assessing *DSM* diagnoses, clinicians administered the *DSM-IV* Checklist (Hudziak, 1998) to family members who were involved in the clinical evaluation of the children. The *DSM-IV* Checklist consists of questions corresponding to each of the criterial symptoms for each diagnostic category. Although the questions are quoted from the *DSM-IV* symptom criteria, clinical interviewers are free to rephrase the questions for the benefit of the interviewees. The score for each diagnostic category is the sum of symptoms judged to be present. For the same diagnostic groupings as used by Gadow et al., the Pearson *rs* with the corresponding *DSM*-oriented scales ranged from .43 for Anxiety Disorders to .80 for ADHD, with mean $r = .63$ (computed by Fisher's z transformation). Recall that the *DSM*-oriented scales do not consist of items reproduced verbatim from the *DSM* symptom criteria. Nevertheless, their mean r of .45 with *DSM* clinical diagnoses and .63 with scores for *DSM* diagnoses on the clinician-administered *DSM-IV* Checklist were significantly higher ($p < .05$) than the mean r of .25 between *DSM* clinical diagnoses and the YI-4 scales that did consist of verbatim *DSM* symptom criteria. This suggests that quantification of *DSM* diagnostic constructs may not be most effectively done by obtaining informants' responses to the verbatim *DSM* symptom criteria.

Bridging Gaps between Nosologically and Empirically Based Constructs

The top-down and bottom-up strategies that characterize nosologically and empirically based constructs, respectively, are arguably the most common approaches to taxonomy of psychopathology. Each makes use of existing knowledge and concepts in different ways. Both may help to advance assessment, taxonomy, and diagnosis, especially if the potential strengths of both can be combined. One way to combine their strengths is to use a common set of assessment procedures for nosologically and empirically based constructs. Such a combination is exemplified by the *DSM*-oriented scales that are scored from the same pool of items from which empirically based syndromes are scored (Achenbach et al., 2004; Achenbach & Rescorla, 2001, 2003). For children, adults, and the elderly, scores for both

types of scales are displayed on profiles in relation to age-, gender-, and informant-specific norms derived from the same national probability samples. The two types of scales have similar psychometric properties, and there are medium to strong associations between some scales of the two types (Achenbach, Bernstein, & Dumenci, 2005; Achenbach, Dumenci, & Rescorla, 2003b). The ability to score both types of scales from the same items that can be rated by the people being assessed and by informants in about 15 minutes makes it easy to compare and contrast nosologically and empirically based findings in many research and clinical contexts for many purposes.

Longitudinal Research Designs

In previous sections, we presented accelerated longitudinal, path, and growth curve designs as examples of research designs that may be especially useful for developmental research related to assessment, taxonomy, and diagnosis. Some longitudinal studies, such as the Dunedin project (Feehan, McGee, Williams, & Nada-Raja, 1995; Newman et al., 1996), have reported *DSM* diagnoses for the same participants at different ages. However, application of powerful longitudinal designs to nosological constructs has been limited by the difficulty of operationalizing nosological constructs via structured diagnostic interviews that need to be repeated on large representative samples of participants over long periods. Additionally, major changes in diagnostic criteria from one edition of the *DSM* to another make it hard to link diagnoses based on the different editions. Finally, although longitudinal growth models can utilize categorical variables such as diagnoses, these categorical variables do not capture as much information about individual differences between people as quantitative scales do.

DSM-oriented scales that can be scored quantitatively from the same brief assessment instruments as empirically based scales provide new opportunities for doing research on nosologically based constructs and for directly comparing the results with those for empirically based constructs. Scores on quantitative *DSM*-oriented scales based on ratings from multiple informants can readily serve as indicators for latent variable analyses. Latent variables estimated from such indicators can then serve as predictors, moderators, mediators, and outcomes in path and/or growth curve analyses. It is thus possible to use accelerated longitudinal, path, and growth curve designs to track relations between developmentally early and later measures of nosologically based constructs to test their developmental stability and the degree to which they predict various outcomes.

Genetic and Other Biological Research

Quantified phenotypic measures of nosological constructs make it possible to test complex quantitative models for genetic and environmental effects on psychopathology. Because these measures can be economically obtained for very large samples of twins and other genetically informative samples, they yield much more powerful genetic analyses than do structured diagnostic interviews, which would be financially prohibitive for such large samples (e.g., Boomsma et al., 2001).

In addition to genetic research, studies of other biological variables can be strengthened by using quantitative measures of nosological constructs. For example, several studies have found significant correlations between the empirically based Aggressive Behavior syndrome and a variety of biochemical measures (e.g., Birmaher et al., 1990; Gabel, Stadler, Bjorn, Shindlecker, & Bowden, 1993; Hanna, Yuwiler, & Coates, 1995; Scerbo & Kolko, 1994). Quantitative scales for measuring nosologically based constructs can provide more powerful and differentiated tests of associations between biochemical variables and diagnostic constructs.

Research on Secular Trends in Psychopathology

It has been widely noted that the previously rare diagnoses of Pervasive Developmental Disorders (PDD), including Autism and Asperger's Disorder, are becoming more common (e.g., Chakrabarti & Fombonne, 2001). Reviews of a variety of documents have also led to the conclusion that adolescent conduct disorders, substance abuse, depression, and suicide have increased (Rutter & Smith, 1995). Secular (i.e., long-term) changes in rates of psychopathology are apt to be very important, because they may provide clues about etiological factors and protective factors. Secular changes in rates of psychopathology may also argue for new efforts at prevention and treatment. Unfortunately, changing rates of diagnoses may reflect changing diagnostic criteria, diagnostic categories, and even the willingness of mental health workers to make certain diagnoses. As an example, Autism was previously blamed on unconscious parental attitudes (e.g., Wolman, 1970, p. vii), which meant that it was a very undesirable diagnosis. In recent years, Autism has come to be regarded as a developmental disability for which intensive services are now provided. Even documentation of suicide may reflect cultural changes, as there is evidence that suicides by young people were previously underreported on death certificates (Males, 1991).

To measure changes in the behavioral and emotional problems on which diagnoses are based, it is necessary to

assess representative samples of the population with the same standardized procedures at different points in time. Problem rates can then be compared to measure changes, whether or not there have been changes in diagnostic criteria, categories, or willingness to make certain diagnoses. As an example, studies in the United States and the Netherlands have used the same standardized procedures to obtain CBCL and TRF ratings of representative samples of children at intervals as long as 23 years (Achenbach, Dumenci, & Rescorla, 2002, 2003a; Verhulst, van der Ende, & Rietbergen, 1997). Completion rates ranged from 82% to 93% in the American samples and 82% to 85% in the Dutch samples. In the American samples, empirically based syndromes and *DSM*-oriented scales showed similar patterns of small but significant increases in problem scores in the 1980s, followed by decreases in problem scores in the 1990s. From 1983 to 1993, the Dutch samples showed little change. A new Dutch sample is being assessed in 2005 (to be updated when data are available).

A study in the United Kingdom compared parents' reports of problems for 15- and 16-year-olds in cohorts that were assessed in 1974, 1986, and 1999 (Collishaw, Maughan, Goodman, & Pickles, 2004). The assessment instruments differed somewhat among the three studies, and only 11 problem items were similar enough for comparison across the three cohorts. Significant increases in conduct problems were found from the 1974 to the 1986 and the 1999 cohorts. Emotional problems and hyperactivity were significantly higher in the 1999 than in the 1974 or 1986 cohorts. Although it is certainly possible that secular trends differ among countries, it is difficult to draw firm conclusions from the U.K. data because of differences in the assessment instruments and because the completion rates were evidently only 62% in 1974 and 45% in 1986 (Collishaw et al., 2004, p. 1353). The 1999 completion rate was evidently not reported, but samples with high completion rates often include larger proportions of people with problems than do samples with low completion rates.

The findings suggest that there has not been a general worsening of children's problems over the past 2 decades in the United States or the Netherlands. Because these studies did not assess children younger than 7 years and did not include many of the symptoms used to define PDD, they may not have been able to detect increases in problems that underlie the increasing rates of PDD diagnoses. However, because the CBCL for ages 1.5 to 5 (CBCL/1.5–5) and the Caregiver-Teacher Report Form for ages 1.5 to 5 (C-TRF) include a *DSM*-oriented Pervasive Developmental Problems scale, it would be feasible to administer the CBCL/1.5–5 and C-TRF to parents, preschool teachers,

TABLE 5.2 Potential Advantages of Quantifying Criterial Features and Taxonomic Constructs

1. Avoids yes/no forced choices about the presence of features and diagnosis of disorders.
2. Allows cut points on distributions of scores that can reflect age, gender, informant, clinical status, and other differences.
3. Provides more precise measurement of psychopathology than categorization does.
4. Allows use of more powerful analytic tools than categorization does for research on patterns of psychopathology, developmental trajectories, behavior genetics, epidemiology, effects of interventions, pharmacokinetics, biochemical variables, and cross-cultural variations.
5. Corresponds to mental representations of taxa in terms of prototypes.
6. Quantified covariation between problems avoids dilemmas of comorbidity between categorical disorders.
7. Facilitates aggregation of multisource data in taxonomic constructs.
8. Provides more precise basis for decisions about treatment and evaluations of progress and outcomes.
9. Facilitates targeting of specific problems in relevant contexts.
10. Measures specific problems independently of criteria for diagnoses.

and day care providers at intervals of a few years to see whether PDD problems are increasing. If scores on the PDD scale do not increase but the prevalence of PDD diagnoses continues to increase, this would suggest that increases in the diagnoses are not accounted for by increases in PDD problems. Such a finding might mean that diagnosticians have become more sensitive to PDD problems or have become more willing to make PDD diagnoses for other reasons. Table 5.2 summarizes potential advantages of quantifying criterial features and taxonomic constructs.

FUTURE DIRECTIONS

Important advances are being made in the developmental study of psychopathology, but much remains to be done. In this section, we outline some future directions for advancing assessment, taxonomy, and diagnosis. Although they are by no means the only important directions, they are particularly important for extending the developmental study of psychopathology to adults, to the elderly, and to more diverse cultures.

Life Span Directions

There are many studies of child/adolescent psychopathology and adult psychopathology. Research on psychopathology among the elderly is also growing rapidly. However, there is far less research on the developmental course of psychopathology from childhood into adulthood and from adulthood into old age. Several factors may be to blame for

the paucity of research that bridges major developmental periods. One factor is that clinicians and researchers tend to specialize in work with children and adolescents, or adults, or the elderly, rather than spanning these different periods. A second factor is that concepts of psychopathology tend to be formulated separately for children and adolescents, for adults, and for the elderly. And a third factor is that assessment, taxonomy, and diagnosis tend to be segmented according to these major periods of life.

To fully understand both adaptive and maladaptive functioning within each period of life, as well as the continuities and discontinuities between periods, we need assessment procedures that provide continuity across broad age spans. Much of the research on prediction of adult psychopathology from childhood variables has used very different measures of child and adult problems. Because certain behaviors that are considered deviant in childhood would not be deviant for adults and vice versa, assessment must be tailored to the developmental level of the people to be assessed. However, methodologically similar measures that include content that is similar for people of different ages, as well as developmentally specific content, are likely to provide better pictures of continuities and discontinuities between developmental periods than are measures that differ with respect to both methodology and content. Our section on "Life Span Applications" illustrated some ways in which similar standardized methodology has been applied to the assessment of psychopathology across major periods of life. However, far more needs to be done to systematically compare and contrast findings for different periods of life and to bridge the gaps between them with longitudinal research. Use of similar standardized methods to assess people as they grow older makes it possible to apply accelerated longitudinal designs, which can yield developmental findings more quickly and cost-effectively than traditional longitudinal designs. For clinical as well as research purposes, similar standardized methods can also be used to assess different generations within families, such as parents and their children, to identify cross-generational similarities and differences.

Multicultural Directions

Globalization has many facets. Although economic globalization may be the most publicized facet, cultural globalization is also important. Cultural globalization stems partly from increasing access to a common set of media for information and entertainment. It also stems from mass movements of immigrants and refugees from their indigenous cultures to very different cultures. Host cultures are

often unprepared to provide mental health and related services to the newcomers. In addition to language barriers, challenges arise from differences in attitudes toward mental health services, as well as from cultural differences in what is deemed to be normal versus abnormal. Other challenges arise when mental health professionals from developed cultures seek to help people in less-developed cultures (Achenbach, Rescorla, & Ivanova, 2005).

Both to build a more comprehensive science of developmental psychopathology and to apply that science to helping more people, it is important to use assessment instruments and data that extend across multiple cultures. Our section on "Multicultural Research" reviewed multicultural findings for psychopathology in children and adults, using both bottom-up and top-down assessment procedures. However, the multicultural studies published to date have mainly assessed psychopathology in terms of syndromes and diagnostic categories developed in Western cultures.

To advance multicultural understanding and applications of the science of developmental psychopathology, it is important to take account of possible cultural variations in the patterning of psychopathology, as well as in the prevalence of particular problems. In the empirically based, bottom-up approach, data from many cultures can be included in the statistical derivation of syndromes. After a multicultural syndrome model has been constructed, data from individual cultures can be tested for goodness of fit to the multicultural model. Although the multicultural model may embody syndrome structures that reflect what is common to the patterning of problems across the different cultures, individual cultures may also be found to differ in certain particulars. For example, data from culture A may not fit the multicultural syndrome model as well as data from cultures B, C, and D. Further testing of the data from culture A may reveal a syndrome that is not found in the multicultural syndrome model. Conversely, other cultures may be found to lack one or more syndromes that are in the multicultural syndrome model.

The process of deriving a multicultural syndrome model and then testing data from individual cultures against the multicultural model can reveal both similarities and differences between the patterns of problems in different cultures. Distributions of scores obtained on the multicultural syndromes by representative samples of people from different cultures can be compared to identify cross-cultural similarities and differences in problem scores on each syndrome.

Because the diagnostic categories of the top-down, nosologically based approach are formulated by panels of mental health experts, one way to take account of multicultural

factors is to include experts from many cultures. However, because many cultures lack indigenously trained experts, the available experts may largely share the Western diagnostic concepts and assumptions that are embodied in current nosologies. It may therefore be worth developing ways that data from multiple cultures can be more directly incorporated into the diagnostic categories of the nosological approach, such as by quantifying diagnostic data from different cultures, as outlined next.

Quantification of Diagnostic Criteria

Nosological approaches typically require categorical yes/no judgments of each criterial feature of each diagnostic category. These approaches also require yes/no decisions as to whether an individual meets the overall criteria for a diagnosis. However, the categorical, yes/no format is not necessarily an immutable part of the nosological approach. In fact, the Nomenclature Planning Work Group for *DSM-V* concluded that it will be “important that consideration be given to advantages and disadvantages of basing part or all of *DSM-V* on dimensions rather than categories” (Rounsaville et al., 2002, p. 12).

A dimensional approach, whereby symptoms are summed to obtain a score for a diagnosis, is often viewed as the main quantitative alternative to the categorical approach. However, summing the number of symptoms is only one of many ways to reap the benefits of quantification for increasing precision and statistical power. For example, allowing diagnosticians to rate symptoms and other diagnostic criteria on 3-step scales rather than requiring yes/no forced choices could make the diagnostic process easier, more reliable, and better differentiated. Categorical cut points could still be retained for deciding whether an individual meets criteria for a diagnosis by specifying diagnostic thresholds in terms of the sum of 3-step ratings rather than the number of symptoms. Further benefits of quantification could be obtained by providing age-, gender-, and culture-specific norms for the distributions of scores within each diagnostic category. For categories in which the distributions of scores differed significantly by age, gender, and/or culture, diagnostic thresholds could be chosen to mark a similar degree of deviance for each group, if desired. Quantification could also be used to combine data from multiple sources as a basis for making diagnostic decisions.

As an alternative to dimensional approaches, person-centered quantification could be used to identify categories of individuals who have similar patterns of problems. Methods for using quantitative diagnostic data to identify types or categories of individuals include latent profile

analysis, cluster analysis, and latent class analysis. A particularly important use of quantification for individual patterns is known as *patient-focused analysis*. This involves repeated measurement of individuals' scores during and after interventions to detect statistically reliable changes in magnitudes and/or slope parameters (e.g., Lambert, Hansen, & Finch, 2001). In short, even elementary quantification, such as rating diagnostic criteria on 3-step scales, could enable the nosological approach to capitalize on the many benefits of quantification that have long been utilized by other approaches to assessment and taxonomy.

Use of Norms to Evaluate Interventions

Numerous studies have been designed to improve prevention and treatment of psychopathology (e.g., Kazdin, 2000, 2003; Kazdin & Weisz, 2003; C. Roberts, Kane, Thomson, Bishop, & Hart, 2003). However, when prevention and treatment are targeted on diagnoses that are assumed to reflect enduring characteristics of the individuals who meet diagnostic criteria, as implied by diagnoses such as ADHD and personality disorders, it is difficult to evaluate the effects of the interventions because the diagnoses are not expected to change. Whether or not particular forms of psychopathology actually involve such enduring conditions, accurate evaluation of intervention effects requires measurement of change from clinical deviance toward the normal range of functioning. To determine whether interventions do produce statistically significant improvements, controlled studies are needed in which norms are used to measure the degree to which participants' preintervention scores move from being clinically deviant to being more typical of scores obtained by representative normative samples of peers (Achenbach, 2001; Kendall, Marrs-Garcia, Nath, & Sheldrick, 1999; Sheldrick, Kendall, & Heimberg, 2001). Because successful adaptation requires not only an absence of problems but also the presence of positive competencies, the effects of interventions should be evaluated in relation to norms for competencies as well as for problems.

Use of Multisource Data

Low levels of agreement between clinical diagnoses and diagnostic interviews, as well as the modest correlations between reports by different informants for both adult and child psychopathology, indicate that no single source of data is likely to suffice for comprehensive assessment of psychopathology. Although assessment of children usually includes data from multiple informants, multi-

informant data are also needed for adults. Even when multi-informant data are obtained, challenges remain with respect to documenting specific similarities and differences between reports by different informants. As an example of ways to compare reports by multiple informants, we have developed computer software that displays data from multiple informants in terms of side-by-side comparisons of item scores and histograms of scale scores (Achenbach et al., 2004; Achenbach & Rescorla, 2001, 2003). The software also displays the degree of agreement between informants in terms of *Q* correlations and compares the *Q* correlations obtained for each case with those obtained for large samples of informants. However, much more research is needed on how best to integrate data from different sources as a basis for decisions about diagnoses, interventions, and outcomes.

SUMMARY

Numerous advances are occurring in knowledge and methods related to developmental issues in assessment, taxonomy, and diagnosis of psychopathology. In this chapter, we defined *psychopathology* as persistent behavior, thoughts, and emotions that are likely to interfere with developmental tasks necessary for long-term adaptation. The major themes of our chapter are summarized next.

First, it has become clear that developmental approaches are needed to understand psychopathology across the life span. This means that we need assessment procedures, taxonomic constructs, and diagnoses geared to the problems characteristic of each developmental period. At the same time, to track developmental sequences and outcomes, continuity is needed between assessment procedures from one developmental period to another.

Second, the developmental study of child and adolescent psychopathology has prompted recognition of the importance of multisource data for adults as well as children. Research has indicated that correlations between adults' self-reports and reports by other informants are as low as those found for children and adolescents.

Third, multicultural perspectives are essential. By applying the same standardized multi-informant assessment procedures in different cultures, we can identify similarities and differences in rates of reported problems to learn whether the same assessment procedures, taxonomic constructs, and diagnoses are applicable in different cultures. Procedures that are found to perform similarly in different cultures can be used to test the course and correlates of psychopathology across the different cultures.

We described developmental methodology that is applicable to the study of psychopathology across the life span. Real-time longitudinal, accelerated longitudinal, path, and growth curve designs are especially useful.

We contrasted nosologically based models of psychopathology that employ a *top-down* strategy (whereby experts formulate diagnostic categories and then choose criteria for the categories) with empirically based models that employ a *bottom-up* strategy (whereby problems scored for large samples of people are analyzed statistically to derive syndromes of co-occurring problems). We explained that *assessment* refers to gathering data to identify the distinguishing features of individual cases, whereas *taxonomy* refers to grouping cases according to their distinguishing features. Prototypes, which represent categories quantitatively in terms of sets of imperfectly correlated features, provide taxonomic models that mesh well with human information processing. We also discussed three different meanings of the term *diagnosis*, that is, *diagnostic processes*, *formal diagnoses*, and *diagnostic formulations*. In this context, we suggested that the high rates of comorbidity found for *DSM* diagnoses raise questions about whether each diagnostic category truly represents a separate disorder.

To advance assessment, taxonomy, and diagnosis, we need to meet the following challenges: test-retest attenuation, that is, the tendency for more problems to be reported at initial than subsequent assessments; limited cross-informant agreement; limited agreement between clinical diagnoses and diagnoses made from structured diagnostic interviews; high rates of comorbidity; great variations in prevalence rates of *DSM* diagnoses made from structured interviews; the need to integrate multisource data; the need to take account of differences related to age, gender, and data sources; and the need to distinguish individual differences from cultural differences. We suggested that quantification of nosologically based constructs could address many of these challenges. Quantification can also make nosologically based constructs more suitable for powerful longitudinal research designs, genetic and other biological research, and research on secular trends in psychopathology.

We then outlined future directions that we feel would advance the study of developmental psychopathology.

In this chapter, we present a model of Comprehensive Psychological Assessment that has been developed to inform the assessment process in both clinical and research settings and has been influenced by the core tenets of developmental psychopathology. Comprehensive Psychological Assessment draws on the tenets of developmental psychopathology at each stage in the assessment process, from developing and honing the question or questions to be addressed, identifying the components of the model that will be actively employed, choosing appropriate instrumentation, interpreting qualitative and quantitative information derived, and ultimately, when appropriate, making and implementing recommendations for prevention, intervention, and public policy. The Comprehensive Psychological Assessment model applies throughout the life span, but in this chapter we illustrate the components and application of the model for children and adolescents.

Researchers and clinicians are accustomed to using hypotheses and referral questions as catalysts for initiating the

assessment process. Following the refinement of hypotheses and questions, the next step is to identify the relevant domains of functioning that need to be evaluated. Within the realm of clinical applications and research focused on developmental psychopathology, it is extremely rare that only one domain of functioning (e.g., expressive language ability) is a sufficient target of evaluation. Because relative strengths and weaknesses in a single domain may or may not be isolated, investigators and clinicians generally recognize the importance of capturing patterns of functioning across multiple developmental domains. For example, without knowledge of a child's general mental level or intellectual functioning, the meaning of below-average performance in one or more additional domains is ambiguous and potentially misleading. More specifically, a below-average score on a measure of receptive language that is administered as a proxy for cognitive functioning could capture low intellectual functioning. However, it could also represent a specific language delay or disorder, a visual attention problem, or a

broader pattern of developmental deviance such as that seen in Autism. Ultimately, patterns of strengths and weaknesses across domains have important implications for understanding developmental trajectories, diagnostic complexities, and contextual influences.

The research or clinical question in combination with pertinent empirical literatures drives the selection of domains that will be the focus of any specific assessment application. Once relevant domains are identified, the careful selection of measures and choice of methods takes place. To capture the most coherent and accurate characterization of the intricacies of an individual's functioning, a currently accepted standard is to utilize a multimethod, multi-informant approach (Johnston & Murray, 2003). In research applications, shared variance attributable to different informants and methods can be modeled statistically using methods such as structural equation modeling (Kline, 1998), and shared variance that is attributable to nested contexts (e.g., family, classroom, school) can be modeled using hierarchical linear modeling (Raudenbush, Bryk, Cheong, & Congdon, 2000). At present, there are newly emerging but few empirical guidelines that clinicians can use for systematically integrating information that spans not only multiple domains of functioning but also multiple informants and methods (Kraemer et al., 2003). Thus, in clinical settings, when informants present differing views about either the child's functioning or features of the child's ecology, the evaluator must predominantly rely on clinical judgment and intuition in the next phase of the assessment process: interpretation of obtained findings. In both research and clinical applications, interpretation of assessment findings can be aided by striving to form conceptualizations and impressions that are grounded in the tenets of developmental psychopathology.

Developmental psychopathology is inherently interdisciplinary in scope and encourages cross-fertilization of epistemologies and methodologies. Cicchetti and Sroufe (2000, p. 256) elegantly state that what is central to the discipline of developmental psychopathology is

to engage in comprehensive evaluation of biological, psychological, social and cultural processes and to ascertain how these multiple levels of analysis may influence individual differences, the continuity and discontinuity of adaptive and maladaptive patterns and the pathways by which the same developmental outcomes may be achieved. (p. 256)

The Comprehensive Psychological Assessment model is designed to press researchers and clinicians to move toward conducting assessments with a grasp of the multiple domains that compose the individual's functioning as well as

the relevant ecologies that transact with the individual's functioning over time. Moreover, we continue to advocate for understanding and recognizing the separate and interwoven relations between current resources and adaptive functioning. Adopting this approach presents both challenges and responsibilities, as clinicians and researchers must embrace multiple complexities simultaneously but still be able to generate meaningful conclusions.

Consistent with one of the thrusts in developmental psychopathology, a major task for clinicians and researchers is to distinguish between adaptive and maladaptive presentations. This can be done only with attention to developmental considerations and an understanding of broader contextual influences. While it is necessary to make use of knowledge about what is normative in each domain at each age or stage, it is not sufficient. The selection of relevant domains and instruments should also be informed by knowledge of both normative and atypical developmental processes relevant to the question or hypothesis posed. This is central when the question or hypothesis to be addressed clearly involves specific diagnoses, developmental disabilities, and categories of psychopathology. More often in clinical settings than in research endeavors, the initial question is too limited and understanding of both typical and atypical developmental processes allows for the expansion or reformulation of the question to one that is more appropriate. For example, if asked to evaluate a preschool child described as phobic of vacuum cleaners, the evaluator would need to appreciate the intensity, frequency, and quality of developmentally normative fears as well as the pathological manifestations of fears in this age group. Although fear of vacuum cleaners may be within normal developmental expectations, the evaluator should draw on knowledge of other psychopathological conditions to determine whether the form and intensity of the behavior is normal or pathological and whether concomitant behaviors exist that would provide evidence of psychopathology (e.g., extreme withdrawal, ritualistic behaviors, necessity for sameness, problems in peer relations).

Across domains of functioning, finding the boundary between normative, at-risk or subclinical, and clinical categories can be challenging, particularly when individual functioning is understood within the multiple contexts that may be influencing current competencies. The developmental psychopathology perspective not only highlights boundaries between normative and psychopathological presentations but also calls attention to the heterogeneous nature of specific disorders and the multiple ways an individual can manifest a particular disorder. Further heterogeneity and complexity emerges because comorbidity in

psychopathological conditions occurs with high frequency (Costello, Mustillo, Erkanli, Keeler, & Angold, 2003). Even if the referral question appears quite narrow (e.g., Does this individual have a learning disability?), a comprehensive assessment strategy addresses multiple aspects of the individual's current development and the manner in which the answer to this specific question may be influencing broader aspects of functioning (e.g., Is the learning disability influencing self-esteem and/or peer relationships?).

In addition to attending to salient domains and interdependence between domains, developmental psychopathology is concerned with the interplay among the individual's neurobiology and genetics, domains of functioning, and ecological contexts. There is recognition that interplay among domains and levels can take many forms, including those that are additive, interactive, mediational, nonlinear, and transactional functions, and that there are bidirectional influences between the individual and the environment (Boyce et al., 1998; Cicchetti, 1990; Cicchetti & Blender, 2004). Research methods are increasingly available to elucidate the nature of the interplay between child and ecological factors (e.g., Sameroff & MacKenzie, 2003). In clinical applications, the Comprehensive Psychological Assessment model serves to compel the evaluator to move beyond a simple description of measured strengths and weaknesses. A more thorough consideration of the manner in which interplay of strengths and weaknesses in specific cognitive, language, sensorimotor, and social-emotional areas may interact with multiple contextual demands to better explain the individual's functioning would minimally entail reflecting on the forms of interplay that might be most explanatory for a particular child or adolescent as well as possible bidirectional and/or transactional influences.

Finally, although evaluators often have only a single snapshot or cross-sectional view of the individual's functioning, developmental psychopathologists advocate for an overarching concern with trajectories and pathways (i.e., continuities and discontinuities). Thus, even when a clinical assessment or research study occurs at a particular point in time, concern with multifinality (i.e., the same risk factors may result in different presentations) and equifinality (i.e., different risk factors may result in the same presentation) is valuable and highlights the importance of obtaining a complete developmental history. A relevant example would be the evaluation of a child who presented with reading difficulties. Longitudinal research has revealed associations between early language impairment, difficulties with letter identification, deficiencies in phonological awareness, and underdeveloped expressive vo-

cabulary among children who are at risk for reading problems or who are reading disabled (cf. McCardle, Scarborough, & Catts, 2001). Also, research findings indicate that reading difficulties run in families (Plomin, 2001). Knowledge of these risk factors would shape the information that a skilled evaluator obtained in the process of taking developmental and family history. In addition, informed by developmental psychopathology, the evaluator might also recognize how risk and protective factors interact and, in essence, that neglecting to ask appropriate and specific questions as part of taking a developmental and family history could negatively impact the child's developmental trajectory. With the reading disability example, failure to diagnose and remediate a reading disability in the early grades can lead to a widening academic achievement gap and more pronounced problems later in elementary school that require a much more intensive intervention program (Lyon, 1996). Indeed, failure to intervene early may place constraints on later academic achievements.

In summary, the tenets of developmental psychopathology guide each phase of the comprehensive assessment process. One could argue that employing a comprehensive assessment process that focuses on multiple domains of individual and contextual functioning is inherently consistent with the tenets of developmental psychopathology. However, it is not adequate to assess multiple domains or contextual levels. The developmental psychopathology lends a three-dimensional perspective of breadth, by examining multiple individual and contextual domains; depth, by orienting the evaluator to stage-salient domains and contextual influences that require greater focus as well as examining these domains with respect to both adaptive and maladaptive features; and time, by recognizing continuities and discontinuities in developmental processes. Finally, the three-dimensional form that emerges from this union of breadth, depth, and time is not structurally uniform at any given point in time as the interplay of domains and contextual influences may vary across development. The Comprehensive Psychological Assessment approach has the potential to enrich the evaluator's perspective on the uniqueness of each child and to promote respect for and valuing of family members, school personnel, and others in the child's nested ecological systems, as they are recognized as playing a significant role in optimizing the child's developmental progress. Moreover, fully embracing this process makes it difficult for the evaluator to maintain a detached stance in part because the evaluator becomes part of the child's nested ecological system and grasps the extent to which the evaluation process is both influenced by and influences the child's current and future functioning.

In addition to building on the tenets of developmental psychopathology, the model of Comprehensive Psychological Assessment presented in this chapter is rooted in earlier work in the study of individual differences in both Europe and the United States. In particular, the assessment field owes much to nineteenth-century scientists who sought to understand mental retardation through the measurement of individuals (Bellack & Hersen, 1980). In 1892, Galton's publication of *Classification of Men According to Their Natural Gifts* provided the foundation for the modern study of individual psychology. Some 35 years later, Alfred Binet developed the first widely accepted test of intelligence used for screening schoolchildren (Binet & Simon, 1905). Binet undertook this task at the request of the French government to provide information for program planning and placement of children who were mentally retarded. Shortly thereafter, in 1910, Goddard, director of the Psychology Laboratory at Vineland Training School in New Jersey, translated Binet's scale into English, a development that launched the large-scale use of individual intelligence testing in the United States. Consistent with our position that assessment of a single domain of functioning is rarely adequate, it is of interest that the diagnosis of mental retardation now requires assessment of multiple domains of functioning. To meet criteria for a diagnosis, an individual must achieve standard scores in both intellectual functioning and adaptive behavior that are at least 2 standard deviations below the population mean (American Association on Mental Retardation, 2002; Battaglia & Carey, 2003).

In presenting the Comprehensive Psychological Assessment model, we do not intend to review the large library of currently available assessment instruments or to instruct the reader in the administration of these instruments. Rather, our aim is to advance the reader's understanding of critical conceptual and theoretical issues that shape the development and implementation of the Comprehensive Psychological Assessment model as well as to challenge clinicians and researchers to become, quoting Kaufman (1994), "intelligent testers." We advocate employing a comprehensive, developmentally sensitive conceptual framework even when pragmatic considerations restrict the range and number of assessment tools that can be employed.

MODEL OF COMPREHENSIVE PSYCHOLOGICAL ASSESSMENT

Deriving partly from a developmental psychopathology framework and partly from our knowledge of the history

and practice of assessment, we have chosen to emphasize that a comprehensive approach to assessment is critical. The investigation of an individual's functioning should be multidimensional, multilevel, and dynamic in nature. *Multidimensional* evaluation is necessary because an individual can rarely be understood through a single score in one domain or subtest or through a global summary score that averages performance across domains (Kaufman & Lichtenberger, 1999). There are myriad major domains of functioning that should be kept in mind as possible targets for assessment. Some of the major domains that psychologists generally consider central to understanding an individual's functioning are cognition, language, academic achievement, motor coordination, and social-emotional development. We also incorporate intraindividual levels and methods of analysis reflecting cellular, genetic, and neurobiological domains (Cicchetti & Blender, 2004; Cicchetti & Dawson, 2002) in our definition of multidimensional. Although various domains of functioning have historically been discussed as if they are independent, interdependence across domains is in fact the norm. Further, skill acquisition and/or deficit in one domain often influences functioning in other domains. *Multilevel* refers to viewing individuals within multiple, nested contexts (Bronfenbrenner, 1986). Nested contexts can be conceptualized in various ways (Bronfenbrenner, 1977; Cicchetti, Toth, & Maughan, 2000) but generally move from those that are proximal to the individual, such as the family, to those that are more distal, such as institutions, community, and culture. Finally, for an assessment to better illuminate critical issues and processes, we suggest that consideration be given to the *dynamic* interplay that occurs among domains within the individual and across levels within the environment as well as between the individual and salient contexts.

Multidimensional Components

One aspect of our model is that assessment needs to be *multidimensional* in nature. Multidimensional assessment rests on first understanding the contribution of the biological substrate of the individual.

Biological Substrate

The biological substrate is always present and inextricably intertwined with observed functioning. New approaches and methods from a variety of disciplines, including molecular and quantitative genetics, radiology, psychoneuroimmunology, physics, and medicine are available for as-

sessing biological contributions to individual functioning. Some of the newer methods that are now being utilized are evaluation of the individual's genome (i.e., allelic variation and cytogenetic abnormalities), structural and functional neuroimaging, and assays designed to measure hypothalamic-pituitary-adrenal (HPA) axis functioning (i.e., salivary and blood cortisol). These advances are facilitating our understanding of transactions between biological and psychological processes. Research findings have started to illuminate the manner in which biology can moderate the impact of stressful life events (e.g., maltreatment; see Cicchetti & Blender, 2004), how traumatic events may dysregulate biological processes (e.g., HPA axis functioning following environmental deprivation associated with Romanian orphanages; Gunnar, Morison, Chisholm, & Schuder, 2001), and that early disruption in brain development can have cascading influences on subsequent development (e.g., Autism and face perception; Schultz, 2005). Currently, these exciting findings have limited bearing on clinical assessments. However, recent molecular genetic and metabolic findings have influenced routine clinical practice. Increasingly, evaluators will refer for genetic, neurological, and metabolic workups when individuals present with dysmorphic features, family history of mental retardation, or growth abnormalities (Battaglia & Carey, 2003). Indeed, an increasing number of individuals who present with developmental delay or mental retardation are now identified as having genetic syndromes and cytogenetic abnormalities.

In conducting a comprehensive assessment, it behooves the evaluator to be familiar with the research and clinical literatures describing individuals with known genetic or neurological abnormalities. Many of these disorders are associated with specific patterns of functioning. For example, children with Fragile X syndrome are reported to have relative weaknesses in tasks requiring sequencing and attention and relative strengths in simultaneous and verbal tasks (Dykens, Hodapp, & Leckman, 1987). Thus, when evaluating a child or adolescent who has a known genetic or neurological abnormality, areas of functioning that have previously been associated with a particular disorder might receive more attention in the evaluation. Moreover, as the field appears to be on the cusp of genetic and neuroimaging breakthroughs regarding genes involved in brain development and cognitive functions (e.g., phonological decoding), neurobiological findings may increasingly guide both assessment and intervention efforts (e.g., Chapman, Raskind, Thomson, Berninger, & Wijsman, 2003; Grigorenko et al., 1997).

It is also important to recognize that knowledge regarding neurobiological functioning provides necessary but insufficient information to fully understand an individual's functioning across developmental domains. For example, knowing that a person has a specific genetic abnormality such as Down syndrome does not provide sufficient information to make predictions about cognitive, academic, or adaptive functioning and does not inform decisions regarding educational and vocational placements. Heterogeneity in the range of functioning across developmental domains has been demonstrated repeatedly in studies of individuals with documented or suspected genetic and neurological abnormalities. Although genetic conditions and neurological difficulties place some constraints on the range of possible outcomes these individuals may achieve, learning or other nonbiologic influences are often more crucial to the individual's current and future functioning.

Current Resources and Functional Adjustment

There are innumerable ways to divide observed functioning. When choosing relevant domains of assessment, there is a tension between selecting a larger number of categories that provide an elaborated view of the child or adolescent (i.e., splitters) and the need to reduce the number of domains to facilitate an efficient, timely evaluation (i.e., lumpers). We consider several primary domains to be of central importance in capturing an overall view of a child's or adolescent's functioning. Consistent with our previous presentation of the Comprehensive Psychological Assessment model (Sparrow, Carter, Racusin, & Morris, 1995), the domains we highlight are cognition, language, social-emotional, sensorimotor, academic achievement, adaptive behavior, and school functioning. These specific domains were chosen for three reasons. First, it is in these areas that the available assessment instruments have attained the greatest scientific rigor and are most likely to provide reliable and valid results. Second, in our clinical experience, a profile of strengths and weaknesses in these aspects of development is most crucial for making determinations regarding intervention strategies and treatment. Third, many of these domains are essential for diagnostic purposes (e.g., cognition and adaptive functioning for a diagnosis of Mental Retardation or cognition and academic functioning for a diagnosis of Learning Disability).

Furthermore, these domains are especially amenable to an assessment approach geared toward distinguishing between the individual's current resources and the adaptive integration of these resources into a functioning whole, which we refer to in our model as *functional adjustment*.

Current resources refer to competencies, skills, and endowments as well as cognitive, social-emotional, and behavioral styles. A developmental perspective enables us to expand the idea of current resources to incorporate not only fully attained competencies or skills but also those that are emerging or are evident only under specific conditions of support or scaffolding. Individuals vary in the degree to which they are able to apply their resources to problems encountered in day-to-day situations. Thus, we differentiate between an individual's capabilities (i.e., resources) and an individual's functional adjustment, or ability to integrate those resources in day-to-day life. Sternberg and colleagues (Sternberg, Wagner, Williams, & Horvath, 1995) have made a similar point in highlighting the importance of assessing practical intelligence in addition to those aspects of intelligence that are captured by traditional IQ assessment instruments. Although it is not possible to evaluate resources and adjustment independently, different assessment approaches place relatively greater emphasis on either individual capacities or adaptive integration.

Our emphasis on functional adjustment outcomes as a means of capturing integrative functioning through psychological assessment differs from other psychological assessment models that typically focus primarily on resources. One means of measuring functional adjustment is through assessment of adaptive behavior, a term that has been equated with daily performance of personal and social sufficiency. A second way to assess functional adjustment is to evaluate how the child or adolescent performs in important everyday contexts such as school. A third way to assess functional adjustment is by making use of measures of impairment that have more typically been part of psychiatric evaluations (Bird et al., 1996; Bird et al., 1990; Canino, Costello, & Angold, 1999). Too often, the emphasis of an assessment is on the individual's capacities or resources without due attention to how these capacities influence behavior in the contexts that compose an individual's "real world."

To illustrate this distinction between current resources and functional adjustment, let us consider the manner in which psychopathological conditions such as Major Depression or Attention-Deficit/Hyperactivity Disorder (ADHD) may contribute to discordance between current resources and functional adjustment. Given the episodic nature of depression, a child may have a typical developmental trajectory prior to onset of the disorder, with consistent competencies across each of the primary domains we include as current resources (i.e., cognition, language, sensorimotor, academic achievement, and

social-emotional). However, with the onset of the depressive episode, there may be a significant decline in the child's ability to perform age-expected tasks of daily living and to be sufficiently motivated to engage in social and academic activities. In this instance, although there may be subtle declines in some aspects of current resources (e.g., performance on timed tasks and tasks involving visuospatial performance), the deterioration in interpersonal relations and school performance (e.g., participating actively in the classroom, completing assignments) is likely to be more dramatic because of the affective and motivational aspects of depression. ADHD presents a different developmental pattern due to the early onset and the nonepisodic nature of the disorder. In the evaluation setting, it would not be unusual for the clinician to obtain a clear picture of the child's or adolescent's current resources. In part, this characterization could be derived because the evaluation setting differs dramatically from most school settings in terms of the presence of a high degree of structure, one-on-one interaction, and limited distractions. However, for an individual who carries a diagnosis of ADHD, there is often a discrepancy between the measured current resources and application of these resources in school, with peers, and in the home (i.e., functional adjustment).

The distinction between current resources and functional adjustment is grounded in developmental psychopathology because there is recognition that the child's overall adaptation in day-to-day settings (i.e., functional adjustment) reflects not only current resources but the interaction of those resources with available contextual supports and affordances. Thus, the current resources are inherently focused on what the individual brings to the child-environment transaction, whereas functional adjustment reflects an integration of what the child and environment bring to the transaction. Further, by broadening the scope of assessment beyond the evaluation setting to include the child's functioning in natural or everyday settings, the evaluator is more likely to learn about risk and protective factors that may exist in the child and environmental contexts. Specifically, research has shown that children who do not yet evidence diagnosable psychopathology but who do evidence impairment (i.e., one form of measuring functional adjustment) are at higher risk for developing a psychiatric disorder (Bird et al., 1996). Although clinicians and researchers most often use functional adjustment measures to capture negative deviations from age-expected behavior, it is our hope that new measures of functional adjustment will be developed that also allow for characteriz-

ing optimal functioning, in part because it is possible that optimal functioning serves as a protective factor in children's development.

***Domains Associated with Current Resources:
Cognition and Social-Emotional Exemplars***

The five primary target domains of assessment in current resources that we emphasize in our model are cognition, language, sensorimotor, social-emotional, and academic achievement; the two functional adjustment domains are school functioning and adaptive behavior. When conducting a Comprehensive Psychological Assessment, it is critical to understand the following aspects of each domain of functioning: (1) the theories that inform major constructs within the domain; (2) how the domain is defined with respect to component parts; (3) developmental characteristics of the component parts, including normative expectations and stage-salient features; and (4) how these component parts can be measured using existing instrumentation at different points in the life span. Because a thorough examination of each of these domains is beyond the scope of this chapter, we present overviews of the cognitive, social-emotional, and academic achievement domains as exemplars of current resources as well as an overview of adaptive behavior to represent functional adjustment.

Cognition. Cognition refers to processes whereby individuals acquire knowledge from the environment. There are numerous views of the nature and development of cognition as well as variation in the number and type of mental processes identified as central to cognition. Across multiple approaches to cognition, including Piagetian, neuropsychological, information processing, and contextual (Flavell, Miller, & Miller, 2002), it is generally recognized that cognition involves both basic and higher-level processes such as attention, perception, memory, reasoning, problem solving, and abstract thinking as well as executive functions such as planning, choosing strategies, and enacting strategies. Although there is overlap between the components and processes associated with cognition and theories of intelligence, it must be clearly stated that we do not consider the term cognition to be a synonym for Intellectual Quotient (IQ) or intelligence. Definitions of IQ generally include the following elements: basic mental processes such as attention and perception, higher-order thinking such as problem solving and reasoning, and adaptation to the environment (Sattler, 2001). However, in practice, IQ represents a summary score on a standardized "intelligence" test that is derived from a combination of scales. These scales measure

some aspects of cognition but are also influenced by functioning in other noncognitive domains, such as fine motor coordination.

Cognition is a broader term that subsumes both functions assessed by traditional standardized IQ tests and other functions that are not included on standardized IQ tests (e.g., learning strategies). In our model of Comprehensive Psychological Assessment, we favor characterizing an individual's cognitive abilities in a manner that draws from cognitive science, neuropsychology, and neuroscience rather than exclusively from a more traditional stance based on theories and notions of intelligence. We have adopted this approach because empirical investigations in these disciplines are advancing our understanding of specific aspects of cognition, such as problem solving, verbal and visual-spatial processing, attention, memory, and executive functions, as well as patterns of strengths and weaknesses that may confer risk or be associated with learning, developmental, and psychiatric disorders. Additionally, there are standardized measures that have been developed to assess each of these components in ways that are more comprehensive than what is obtained from IQ testing alone. Finally, by making use of multiple but overlapping measures of cognitive functioning, the clinician or researcher can look for consistencies and inconsistencies in the pattern of findings and generate more robust interpretations. The Cross-Battery approach (Flanagan & Ortiz, 2001; McGrew & Flanagan, 1998) is a formalized system for performing cognitive assessments in this manner.

Despite the pitfalls of relying solely on intelligence tests to capture an individual's cognitive functioning, it is still necessary to use these tests. It is encouraging that in recent years several of the major intelligence tests (i.e., KABC-II: Kaufman & Kaufman, 2004; SB5: Roid, 2003; WPPSI-III: Wechsler, 2002; WISC-IV: Wechsler, 2003) have undergone substantial revision. Some positive trends in the construction of these tests are evident, such as expanding the number of factors used to characterize intelligence and incorporating tasks that purport to access more novel problem solving and thereby also provide information about future learning potential (e.g., KAIT: Kaufman & Kaufman, 1993; KABC-II: Kaufman & Kaufman, 2004). Because IQ measures are derived from multiple subtests and are therefore multifactorial and complex, an analysis of the underlying contributing components in the test is required for adequate interpretation and is often more informative than reporting a global IQ score. We advocate interpreting cognitive tests that comprise multiple subtests or scales using profile analysis of relative, statistically and/or clinically

significant strengths and weaknesses within IQ tests. Controversy regarding this practice continues, with advocates for (e.g., Carroll, 2000; Davison & Kuang, 2000) and against (Watkins, 2000) profile analysis. While advocating for the use of profile analysis, we recognize that care must be taken to avoid overinterpretation of observed discrepancies that may reflect systematic or nonsystematic error variance. This is done best when discrepancies are interpreted in the context of other data about the child or adolescent (Davison & Kuang, 2000).

In the cognitive domain, initial characterization of the individual's functioning may be derived from the information generated from intelligence tests. However, we also suggest that assessment of cognitive abilities and problem-solving style at minimum requires consideration and possibly examination of attention, perception, memory, and executive functions. The extent to which these basic and higher-order mental processes are examined will be determined by the questions or hypotheses at hand. Regardless of whether it becomes necessary to directly evaluate the child's or adolescent's skills in these areas, it is important for researchers and clinicians to have an understanding of these cognitive subcomponents.

Attention is a process that involves orienting, selecting, and sustaining focus on relevant information in the environment and ignoring competing, irrelevant information (Mirsky, Anthony, & Duncan, 1991; Posner & Petersen, 1990; Rothbart, Posner, & Hershey, 1995). Thus, a child or adolescent must demonstrate the capacity to sustain attention by maintaining his or her focus on the important dimensions of the task presented without being distracted or pulled off-task by unimportant dimensions. To accomplish this focus, the child or adolescent must simultaneously ignore a wide range of environmental happenings and details, including both external and internal stimuli. Attention is considered to be a limiting front-end feature of the perceptual process that controls the amount and quality of the information available for higher-order cognitive processes (Rothbart et al., 1995). The development of the attention system is undergoing particularly rapid and qualitative changes during the early childhood years. As children advance from infancy to early childhood, there is increased efficiency in terms of making use of orienting and selecting strategies as well as enhanced ability to sustain attention and ignore distracters (Ruff & Lawson, 1990; Ruff & Rothbart, 1996). Ultimately, attention is a critical prerequisite for the successful performance of more complex cognitive processes.

Perception is considered to be another step in the processing of sensory/attentional information. Across modalities,

perception involves detection, discrimination, and localization (Sparrow & Davis, 2000). Information that is perceived through sensory systems is then transformed into higher-order codes for use by the various higher-order cognitive subsystems. Although there are multiple sensory systems, the process of transforming information from the visual and auditory systems into higher-order codes has been extensively investigated (Kolb & Whishaw, 2002; Lezak, 1995; Temple, 1997). In turn, this perceptual material informs higher-order cognition such as representation, categorization, and formation of early concepts.

Memory is another aspect of cognition that should be examined as part of a comprehensive assessment. Memory is considered to be the set of processes that temporarily holds new information while it is being utilized or processed for other purposes (short-term memory) or more permanently holds learned information for future reference and use (long-term memory). It is also useful to distinguish between declarative memories or facts accessible to conscious recall (i.e., knowing that) and procedural memories or automatic operations and skills (i.e., knowing how; Kolb & Whishaw, 2002). Some models of memory (Atkinson & Shiffrin, 1968) emphasize that information is momentarily entered into the sensory register and then transferred to short-term memory that has limited capacity. For material to reach long-term memory, strategies such as rehearsal need to be applied to the information in immediate short-term memory. Recently, there have been efforts to draw on current models of memory (Baddeley, 1992; Cabeza & Nyberg, 2003; Engle, Tuholski, & Laughlin, 1999; Squire & Schacter, 2002) to refine specific measures of memory (e.g., WRAML-II; Sheslow & Adams, 2003) as well as those measures that are incorporated into standardized tests of intelligence (e.g., SB5; Roid, 2003; WISC-IV; Wechsler, 2003) and of phonological processing (e.g., CTOPP; Wagner, Torgesen, & Rashotte, 1999).

Another critical aspect of cognition is the executive functions. The term executive functions has a number of definitions (cf. Zelazo, Carter, Reznick, & Frye, 1997) but includes those control and regulatory processes that (1) integrate information perceived in the external world and transform perception into higher-order symbols, (2) compare incoming information to what is stored in memory, and (3) combine the incoming perceptions with information about the person's internal physiological state and biological drives. In addition, the executive system guides the determination of appropriate behavioral responses to a given situation by (1) deciding on appropriate goals, (2) developing plans to meet those goals, and (3) organizing the required

behavioral programs to carry them out. Executive functioning is probably the most complex aspect of the cognitive module because a variety of higher-order cognitive functions are required to select, plan, organize, and implement a behavioral response appropriate to a constantly changing world. Because of this complexity and the degree to which these skills are interwoven with other aspects of cognition, our understanding of and ability to assess this set of abilities in children and adolescents has evolved gradually. However, in the past decade, ongoing clinical interest and empirical investigations have enabled the development of promising standardized measures (e.g., D-KEFS: Delis, Kaplan, & Kramer, 2001; BRIEF-Preschool Version: Gioia, Espy, & Isquith, 2003; BRIEF: Gioia, Isquith, Guy, & Kenworthy, 2000; NEPSY: Korkman, Kirk, & Kemp, 1998). When cognition is assessed in a more comprehensive manner such that multiple measures of the various subcomponents of the cognitive system are employed, the researcher or clinician has the subsequent challenging task of interpreting and integrating both qualitative and quantitative findings. To the extent that standard measures were available for use and consistencies emerged in support of a meaningful pattern of strengths and weaknesses, this approach can illuminate the cognitive contributions that are operating for the individual.

Nevertheless, making use of profile analysis not only within but also across instruments is controversial. Different assessment instruments have unique psychometric properties and the normative groups used may be quite dissimilar with respect to factors such as age bands of comparison, representativeness of the normative sample, and construct validity. Although tests also vary with respect to reliability, it is possible to incorporate the reliability of different assessment instruments when making profile comparisons. Still, we suggest that in the hands of a skilled clinician, research specialist, or practitioner-scientist, the process of combining findings from sufficient but independent sources of measurement and subjecting the data to profile analysis has added and will continue to add materially to our understanding of the *differential* patterns of cognitive functioning that distinguish among clients with *similar* overall levels of cognitive functioning.

Social-Emotional Functioning. Comprehensive understanding of an individual's functioning also necessitates characterizing social-emotional competencies, vulnerabilities, and deficits as well as social-emotional and behavioral problems, symptoms, and disorders. Traditional approaches to assessing social-emotional functioning have focused on identifying whether an individual is exhibiting prominent deviations from social-emotional expectations, such as wor-

rying to excess, showing a lack of pleasure and/or heightened feelings of sadness, exhibiting patterns of relating that are atypical and/or lack stability, and interpreting situations in a distorted fashion. Making determinations about the presence of such extreme or deviant behaviors and their duration, intensity, and quality is critical in terms of accurately identifying disorder for the purposes of diagnosis and, ultimately, treatment. However, guided by a developmental psychopathology framework, the assessment of social-emotional functioning is recognized as a more encompassing endeavor for several reasons. First, the emphasis expands to allow for delineating not only social-emotional deficits but also competencies, subthreshold manifestations of symptoms, and risk factors. Second, deficits, risks, and competencies are understood in a developmental context, meaning that the child's developmental stage and negotiation of salient age-appropriate tasks are considered. Third, distinctions are made as to whether social-emotional development is following a normative trajectory, occurring in a gradual but typical manner resulting in underdeveloped or immature functioning, or whether there are atypical or deviant features that indicate a developmental trajectory consistent with a marked disability (e.g., Autism, Schizophrenia).

In many respects, traditional approaches to the assessment of social-emotional functioning have been limited by an overemphasis on diagnostic considerations as well as a historical reliance on projective measures. Although making diagnostic determinations and characterizing an individual's understanding of ambiguous stimuli can be informative for understanding the individual's current functioning and making intervention recommendations, we argue that assessment in this domain should be more securely rooted in our understanding of social, emotional and behavioral development as well as the extent to which these realms are inherently intertwined. To do so, it is incumbent on researchers and clinicians to develop a clear, coherent, and contemporary framework for social-emotional functioning.

Because the current body of research on social and emotional development is vast, it has been challenging to identify core facets of this domain that can be evaluated in a reliable and valid fashion. Nevertheless, theories and studies of social-emotional development do provide some guidelines about such core facets. Studies of the emotional component of the social-emotional domain have focused on the following types of processes: (1) emotional milestones (e.g., recognizing and labeling facial expressions, understanding of emotions); (2) intensity, frequency, and quality of emotional reactivity and expressiveness; and (3) emotion regulation/coping. Studies of the social component of

the social-emotional domain have focused on (1) the acquisition of discrete relational skills, such as joint attention and specific social skills (e.g., sharing); (2) interpersonal relationship processes, including interpersonal styles, behaviors such as direct and relational aggression, and knowledge about friendships; and (3) peer group processes (e.g., teasing, classification of popular, peer-rejected, and peer-neglected children). Furthermore, it is useful to delineate the meaning of social and emotional competence. Denham and colleagues (2003) have posited that emotional competence is composed of emotional expressiveness, emotion knowledge, and emotion regulation. Rose-Krasnor (1997) posits a multilayered framework that rests on the theoretical concept of effectiveness in interaction, offers a second tier that delineates the contributions of context as well as self and other perspectives, and rests on basic skills and motivations. Cole and colleagues (Cole, Martin, & Dennis, 2004) focus on both normative and psychopathological processes inherent in emotion regulation.

At this point in time, these facets may serve to organize the evaluation of a child's or adolescent's social-emotional functioning but cannot necessarily be measured in a reliable and valid manner because few appropriate standardized normed assessment tools of this nature have been developed. Our current knowledge of age-expected performance of specific competencies and the range and variation of social and emotional functioning among children and adolescents is extremely limited. Large-scale representative studies (i.e., epidemiological research) as well as development and norming of new or existing clinical measures are needed. Indeed, the few normed clinical instruments that are available focus almost exclusively on symptoms of social-emotional and behavioral disorders with increasing, albeit restricted, attention to competencies. These assessment instruments fall into the broad categories of behavior rating scales (e.g., Child Behavior Checklist [CBCL]: Achenbach, 2001; Achenbach & Rescorla, 2000, 2001; ITSEA: Briggs-Gowan & Carter, 1998; Carter, Briggs-Gowan, Jones, & Little, 2003; BASC: Reynolds & Kamphaus, 1992) and structured and semistructured diagnostic interviews (e.g., CAPA: Angold, Cox, Prendergast, Rutter, & Simonoff, 1987; DISC IV; Shaffer, Fisher, Lucas, Dulcan, & Schwab-Stone, 2000; PAPA: Egger & Angold, 2004). Information about a child's or adolescent's social-emotional functioning can also be obtained from adult caregivers such as parents and teachers, from the child, and/or from clinical observation in the evaluation context and in more naturalistic environments such as at home or at school. One promising avenue in the

evaluation of social-emotional functioning is the development of structured observational diagnostic tools (e.g., ADOS: Lord et al., 2000; DB-DOS: Wakschlag et al., 2002, in press) that can be used in conjunction with checklists and interviews. To date, these instruments are quite specialized in the sense that they are most relevant when the evaluator has targeted a particular diagnostic category and when evaluating young children or individuals with limited capacities to verbally express or reflect on their own social and emotional functioning and behaviors.

Empirical advances in understanding other aspects of adaptive and maladaptive social-emotional processes have been slow to affect clinical assessment, although some influences are evident. The influences may gradually take root when clinicians adopt new terms and concepts and/or when newly standardized measures that have drawn directly from current research become available. For example, increased understanding of the temperament dimension of behavioral inhibition and its relation to the emergence of anxiety disorders (Biederman et al., 2001; Hayward, Killen, Kraemer, & Taylor, 1998; Rosenbaum et al., 2000; Schwartz, Snidman, & Kagan, 1999) has facilitated the willingness of psychologists and other mental health professionals to consider that a young child may be having difficulties due to early emerging anxiety and has informed the development of measures such as the Infant-Toddler Social and Emotional Assessment (ITSEA) that includes both a General Anxiety Scale and an Inhibition to Novelty Scale within the Internalizing Domain (Carter et al., 2003).

We view the continuum of social-emotional adjustment as ranging from optimal functioning to clinical disorder. Between these two fuzzy categories are gradations with diffuse boundaries. The continuum includes age-adequate/average, temperamental variation that may place a child at risk for later psychopathology, and subthreshold/subclinical. Given the current state of knowledge and limited availability of standardized assessment instruments, judgments regarding where on the continuum children and adolescents fall is largely a matter of clinical judgment. Standardized assessment tools are still predominantly restricted to problem and competence checklists and measures of adaptive functioning (that may serve as a proxy for impairment). Other forms of assessment such as structured and semistructured diagnostic interviews that have adequate reliability and validity and can contribute critical information to a clinical evaluation are too rarely administered because of time constraints and training issues. To enhance understanding of the social-emotional continuum and the boundaries between categories along

the continuum, studies that utilize epidemiological sampling techniques and/or national standardization sampling frameworks are needed.

Academic Achievement. Almost all achievement assessment is focused on evaluating an individual's current skills and factual knowledge. Skill development is the primary focus in the early school years, with most achievement assessment focused on basic reading decoding and comprehension, spelling, writing, and arithmetic skills. As children progress into the later primary grades and through high school, assessment of skill development is still important, but the assessment must be broadened to include an evaluation of specific areas of knowledge (e.g., science, social studies, history). When a child or adolescent experiences difficulties in basic academic skill areas, it can be useful to administer more specialized tests that examine the component skills required to achieve in a basic academic skill area. Due to recent policy interest in reading as a gateway to broader academic achievement as well as studies of the genetics of reading disabilities that emphasize component processes, a number of tests are available that provide more specialized assessments of the elements that support reading ability (e.g., identification of letter-sound relationships, phonological awareness, phonemic segmentation and blending). The Comprehensive Test of Phonological Processing (CTOPP; Wagner et al., 1999) is one example of an assessment tool that addresses phonological processing that may underlie risk for reading disabilities. These more specialized measures of reading disability highlight the heterogeneity of reading disabilities and emphasize the varied developmental pathways that can result in a reading disability (cf. McCardle et al., 2001). Standardized, normed instruments to address mathematical skills and writing have not reached a similar level of sophistication. However, there are measures available that break down the component skills required to achieve in the areas of mathematics and written expression. For example, the KeyMath (Connolly, 1998) distinguishes among basic concepts (e.g., numeration, geometry), operations, (e.g., addition, division), and applications (e.g., measurement, estimation).

Academic achievement represents the outcome of very specific areas of formal learning. Typically, achievement assessment is focused on academic-related abilities gained in formal learning environments such as school. These assessments almost always represent the implementation of what a child or adolescent has acquired from educational opportunities and are therefore affected by cultural, envi-

ronmental, and curricular exposure. Here we are limiting academic achievement to the individual's learned capacities rather than the degree to which these abilities are employed in everyday settings.

Domains Associated with Functional Adjustment: Adaptive Behavior Exemplar

The goal of determining how the domains of development affect a child's or adolescent's everyday life (e.g., school performance, peer relationships) is inherent in any assessment, yet the examination of an individual's performance of age-appropriate tasks in everyday settings such as school and home is often neglected. The two domains that have received more attention with respect to day-to-day performance and whether performance meets culturally imposed age expectations are academic functioning in the classroom and adaptive behavior across settings. We highlight adaptive behavior in this chapter as there are well-standardized, norm-referenced measures developed for this domain.

Adaptive Behavior. Adaptive behavior primarily has been considered an important domain for the classification of mental retardation (Sattler, 2001). However, in our clinical and empirical work with children and adolescents who vary widely in terms of cognitive level and psychopathology, we have become convinced of the contribution that adaptive behavior offers to comprehensive assessment of all populations, not only those suspected of functioning in the mentally retarded range. We have found adaptive behavior particularly useful for describing decrements in day-to-day functioning associated with learning disabilities and psychiatric conditions.

Adaptive behaviors are typically thought of as sets of concrete behaviors that reflect personal and social sufficiency in day-to-day life at home, in school, and in the community (Sparrow, Balla, & Cicchetti, 1984). In discussing the multifactorial structure of adaptive behavior, Schalock (1999) offers the following components: (1) gross and fine motor or physical skills; (2) independent daily living skills such as dressing, bathing, cooking; (3) cognitive, communication, and academic skills such as reading, writing, managing a checkbook; and (4) social competence skills requiring establishing and maintaining friendships as well as social reasoning and comprehension. These categories mirror the domains that are assessed by the Vineland Adaptive Behavior Scales (Sparrow et al., 1984), including the following domains: communication, daily living skills, socialization, and motor skills.

Acquiring information concerning adaptive behavior skills provides a window into the individual's ability to integrate current resources across developmental domains in the contexts of daily life. Mastery of stage-specific tasks will be manifest in the practical negotiation of the everyday integration of domains such as cognition, language, social-emotional functioning, and academic achievement. Deficiencies in communication, socialization, and daily living skills often appear as a function of cognitive delay or an emotional disturbance. It is important to note that there is not a one-to-one correspondence between cognitive and adaptive functioning, although stronger associations will be observed for individuals at the lower end of the cognitive continuum. Also, a child's or adolescent's linguistic and cognitive level will place some constraints on his or her adaptive behavior skill level. Psychiatric symptoms such as social withdrawal, oppositionality, depression, and anxiety can interfere with a child's or adolescent's ability to perform routine behaviors (e.g., making a bed, interacting with friends in social settings, bathing, crossing a street independently). Determining if a deficit in adaptive behavior is the result of a social-emotional disturbance, is associated with cognitive limitations, or reflects both social-emotional and cognitive contributions is important in making appropriate intervention recommendations. At the same time, it is essential to recognize that adaptive behavior is modifiable and that teaching an individual how to behave in an age-adequate manner is likely to exert reciprocal influences on other developmental domains. Distinguishing skill deficits from motivational deficits is central to appropriate intervention planning. It is also important to be aware that some children will have very low adaptive functioning because they are not expected to engage in age-appropriate adaptive behaviors, particularly in the domain of daily living skills (e.g., making their bed, assisting with chores). Knowledge of the most central tasks of development, coupled with an adaptive behavior profile, provides a vehicle for evaluating the individual's practical integration of competencies across developmental domains.

Thus, whereas development in cognition, language, social-emotional, and motor domains drives the acquisition of adaptive behaviors, adaptive behavior in this model is largely thought of as the end result of how well a child or adolescent integrates these domains in everyday life. For this reason, adaptive behavior may provide a vehicle for measuring a very challenging area within the social-emotional domain, childhood impairment, which is also referred to as disability, psychosocial or functional impairment, or limitations (Pickles et al., 2001; Simeonsson et al.,

2003). To the extent that a decrement in adaptive behavior can be quantified using existing interview and checklist assessments of adaptive behavior, it may be possible to also quantify disability or impairment associated with psychiatric disorder in childhood and adolescence.

Multilevel, Contextual Components. The Comprehensive Psychological Assessment approach not only considers individual functioning from a multidimensional perspective but also places the individual in multiple, nested contexts (Bronfenbrenner, 1986). These contexts can be conceptualized in various ways (Bronfenbrenner, 1977; Cicchetti et al., 2000) but generally move from those that are proximal to the individual, such as the family and peers, to those that are more distal, such as institutions, community, and culture. It is important for clinicians and researchers to be aware of the major spheres of contextual influences, such as the family, peers, institutional settings (i.e., day care, school, afterschool), and culture. As well, they should be developmentally informed, able to detect features of specific contexts that might promote or hinder development at particular ages and/or stages. Theorists and researchers in the field of developmental psychopathology have made strides toward establishing a better understanding of the nested ecologies that transact with individual functioning to affect development. At the more proximal levels of family and peers, methods exist for systematically examining parent-child interactions, parenting styles, quality of parent-child relationships, direct as well as indirect family processes, peer interactions, friendships, social status, and peer group processes. At the institutional level, the settings that have received the most empirical attention are day care, Head Start, school, and afterschool programming. Measures that have been developed to assess these settings focus on qualifications of the adults who are interacting with children (e.g., educational background, certifications); adult-child ratios; environmental characteristics, including safety features; developmental appropriateness of materials available to children; and qualities of caregiver-child relationships and interactions (Friedman & Amadeo, 1999; Rutter & Maughan, 2002). Gathering information about the quality of out-of-home environments that involve nonparental relationships and how these may transact with family processes is necessary to our understanding of how to ensure that typically developing children have access to quality environments that foster competencies and that children who are at risk or manifesting problems have access to appropriate interventions implemented in the same or similar settings.

Another contextual level that we are now recognizing, defining, and measuring in more sophisticated and meaningful ways is community. Innovative work has been conducted to quantify multiple aspects of community, including social cohesion (e.g., Silk, Sessa, Sheffield Morris, Steinberg, & Avenevoli, 2004), community violence exposure (e.g., Gorman-Smith & Tolan, 1998), and neighborhood characteristics as distinct from family-level poverty. This work has capitalized on advances in demography, applying aggregated census data to individual families in specific block codes as well as innovative observational and qualitative ethnographic methods that permit careful characterization of subtle qualities of neighborhood experience (e.g., Leventhal & Brooks-Gunn, 2003).

Bringing multilevel contextual considerations to bear in the assessment process can easily become unwieldy for the researcher or clinician. Further, when there is risk at one level of the broader ecology, there is an increased likelihood of risk across multiple levels of the broader ecology (Sameroff, Seifer, & McDonough, 2004). Consideration should be given to the manner in which risk factors may exert influence on child functioning, including both direct and/or indirect mechanisms. Recent studies highlight that more distal influences are often mediated by proximal influences in the family (Rutter, 2005). Further, it is now clear that individual factors can moderate the impact of contextual influences such as stressful life events or cumulative risk. Examples include moderation of stressful life events by genetic endowment (Caspi, Sugden, & Moffit, 2003; Rutter, 2005) and moderation of cumulative risk by security of attachment (Belsky & Fearon, 2002) in the prediction of psychological adjustment. Although individual factors may improve probabilistic outcomes through moderation, it is important not to revert to blaming the victims of sledgehammer environmental conditions that fail to meet acceptable human standards, such as exposure to neighborhood violence and wartime conditions.

Contextual Levels: Family and Culture as Exemplars

In this section, we discuss family and cultural levels within the multilevel contextual system as examples of the manner in which relevant aspects of levels can be identified and relevant developmental processes considered as they relate to assessment.

Family. Understanding the family context is a complex undertaking because there are numerous family features and factors that are relevant to understanding the individual's functioning. From a systems perspective, families are

"complex structures comprised of interdependent groups of individuals. Members of a family system devise strategies for meeting the needs of individual family members and the group as a whole" (Carter & Murdock, 2001, pp. 8–9). This definition points to the necessity of first characterizing a family in terms of features, such as who is considered a member, how many members make up the group, and the gender and age of each family member. In the process of obtaining this information, the clinician will also start to identify the "family form." As Carter and Murdock point out, the nature and organization of families has changed substantially since the 1960s. Although myths persist that the family is synonymous with a heterosexual, two-parent household, the reality is that there has been an increase in both single-parent households and gay and lesbian single-parent and two-parent households (Black, Gates, Sanders, & Taylor, 2000; U.S. Census Bureau, 2000), as well as increasing recognition of the role that close relatives such as aunts, uncles, and grandparents may play in caretaking and child rearing (Dressler, 1985; Wilson & Tolson, 1990).

Descriptive features of the family context are a reasonable starting point for shaping a conceptualization about the influence the family may have on a child or adolescent, yet care should be taken to gather additional information that sheds light on what factors contributed to the current family form. For example, a child may be living in a family headed by a two-parent household that has been stable in terms of membership but stressful due to parent conflict. Alternatively, the two-parent household might be a second marriage that is amicable and in which socioeconomic status has improved. In the first example, the potential positive influences of family stability and two-parent heads of household may be overshadowed by the more concerning, chronic exposure to intense anger expression and verbal hostility during parent conflicts (Cummings & Davies, 1994, 2002). In the second scenario, concerns about the effects on a child being raised by a stepparent might be less informative than knowing that in this reconstituted family the child is deriving benefits from an improvement in socioeconomic status and an affectively positive family climate.

Quality of relationships within the family are central to multiple domains of children's functioning. From a family life cycle perspective, parent-child interactions are highly salient in early childhood and continue to play a role in child social competence through adolescence (Weinfeld, Ogawa, & Egeland, 2002). However, different dimensions of parenting appear to be more or less important depending on the domain of child functioning and the age or stage of the child's development. Broader characteristics of family

climate, including communication styles, affective tone and expressiveness, warmth, cohesion, and adaptability, can also be assessed with both questionnaire and observational methods and have been shown to influence cognitive and social-emotional outcomes for children.

Central dimensions of family that are routinely assessed in the developmental psychopathology literature include observations of parent-child interactions as well as parent reports of parenting stress and marital satisfaction and parent and child reports of parenting styles, communication, and overall family functioning. From the assessment perspective, it is important to recognize that associations with most dimensions of family and child functioning assessed have been found in normative, psychopathological, and developmental disability populations. At the same time, unique issues need to be addressed at different points in the family life cycle and when families are facing unique life transitions or events (e.g., the recent diagnosis of a child with a disability or chronic health condition). Specialized assessments have been developed and are often needed for understanding how individuals within families adapt to specific life stressors and transitions (Reaction to Diagnosis Interview: Pianta & Marvin, 1992) and the kinds of accommodations they employ. Many brief checklists are available that address family functioning in clinical evaluations. However, in most cases, the family brings an identified child as the target of an evaluation and will be surprised if asked to respond to questions about broader family functioning. Administering family questionnaires to the parents, child, and/or siblings requires the evaluator to convey to the family the importance of understanding proximal contextual factors in the child's adaptation. Unfortunately, most clinical training does not encourage the use of family measures as a part of a child clinical or neuropsychological evaluation. Indeed, one of the few situations in which the clinician is compelled to address family relationships is in the unfortunate circumstance of maltreatment or neglect.

Culture. As societies around the globe become increasingly diverse, researchers and clinicians must increase their competence with respect to understanding variations in culture, the role of culture in both typical and atypical developmental patterns, and the need to integrate the cultural context of the evaluation into the comprehensive assessment approach. With respect to our Comprehensive Psychological Assessment model, knowing about a child's or adolescent's cultural background may inform the selection of tests to assess relevant domains, the manner in which the evaluator approaches the child and family about

their current concerns, and the interpretation of behavioral observations and quantitative test findings. Adopting the view that for each of us, whether we are assuming the role of clinician or researcher, acquiring cultural competence is a self-work in progress is particularly critical given the influence of immigration on demography and the fact that the manner in which culture is defined and understood in institutions such as the field of psychology has changed significantly in recent history (see Garcia Coll, Akerman, & Cicchetti, 2000) and will continue to change.

One general definition of culture refers to shared values, beliefs, and practices that are transmitted across generations within a group (cf. Pinderhughes, 1989). It is important to distinguish culture from race and ethnicity and to recognize that the most recent population genetics findings support that there are no discrete boundaries between racial groups (Rosenberg et al., 2002). Although it is possible to identify small group differences between populations, most of the variability across all humans comes from within-population differences (Rosenberg et al., 2002). Indeed, race may be best defined as a social construct employed within social relationships for classifying and distinguishing among individuals according to physical characteristics (Suyemoto & Dimas, 2003). Ethnicity refers to a particular kind of culture that is usually associated with a common geographic region or national origin (Pinderhughes, 1989). Understanding the role of culture in development is becoming more complex in part because families are increasingly multiethnic, multicultural, and multiracial. There are also wide variations in acculturation patterns within and across ethnic, cultural, and racial groupings. For example, the number of multiethnic children has steadily increased over the past 30 years (U.S. Census Bureau, 2000). Moreover, consistent with our view of nested ecological contexts as applied in the Comprehensive Psychological Assessment model, it is critical to recognize that culture is not a static entity but is dynamic and responsive to the settings and conditions to which the family must adapt (Christensen, Emde, & Fleming, 2004). Thus, family rituals, day-to-day routines, and religious and household practices through which culture is maintained and transmitted across generations are influenced by factors such as immigration patterns, economic conditions, and exposure to other cultural groups.

Scholars who study cultural influences on development advocate that cultural beliefs, values, and practices be a central focus of assessments of children (Betancourt & Lopez, 1993; Christensen et al., 2004; Garcia Coll & Magnuson, 2000). This presumes that researchers and clinicians acquire training in culturally competent assessment

practice. In addition to openness to and celebration of diversity, researchers and clinicians must engage in a process of self-awareness to avoid biases that could lead to over- or underpathologizing the child or family practices and beliefs. Because cultural differences can exacerbate an already complex power dynamic between the assessor and the assessed, cultural proficiency is central to gathering reliable and valid information. For an extensive discussion of cultural competence, see the American Psychological Association's (2002) *Guidelines on Multicultural Education, Training, Research, Practice, and Organizational Change for Psychologists* (<http://www.apa.org/pi/multiculturalguidelines>). Also, Christensen et al. (2004) offer some excellent suggestions for integrating awareness of family culture when conducting a young child assessment. Specifically, they recommend talking with families about the following: (1) perceptions of the child's difficulties or distress, (2) how the child's behavior is viewed relative to other child behavior in their cultural group, (3) cultural explanations for the child's difficulties or distress, and (4) parental experiences with and preferences for treatment.

Issues of culture are often directly relevant to the appropriateness of a particular instrument for a given individual or target group. A potentially complicated issue that is related to culture is that of assessing multilingual individuals. It is not sufficient to employ a measure that has been translated into the target population's or client's native language because the translation may not be appropriate for the population under study or the family seeking treatment. Although translation and back-translation have traditionally been held as a standard, it is not a sufficient practice because there is no guarantee that the psychometric properties of the instrument will remain stable across cultural, racial, or ethnic groups. Whether an instrument has been translated into a new language or is going to be used with a cultural, ethnic, or racial group on which it was not normed, evaluating cultural appropriateness is often facilitated through the use of focus groups and/or pilot testing in the target population. This strategy can provide feedback on content validity, particularly with respect to going beyond the quantitative data that inform whether measures evidence similar scale structure across groups and whether patterns of expected associations with both related and unrelated constructs (i.e., convergent and discriminant validity) are observed. Indeed, when evaluating cultural bias, it is insufficient and often misleading to review item content. Although documenting that a test or scale evidences comparable scale structure and internal consistency is useful, the evaluating bias requires determining whether or not a

test functions in the same manner across groups (e.g., has the same sensitivity and specificity; Sattler, 2001). In addition, because it is rare to obtain appropriate within-ethnic group reliability and validity data, investigators who are working with minority populations are encouraged to report internal consistency statistics when presenting findings. It is not appropriate to assume that the internal consistency or factor structure obtained in a dominant culture population will be comparable when a scale is employed with ethnic/racial minority groups.

McCain and colleagues (McCain, Kelley, & Fishbein, 1999) conducted a study with the Toddler Behavior Screening Inventory (TBSI) that highlights the importance of attending to possible response differences across ethnic/racial groups. Specifically, they examined patterns of responding on the TBSI comparing Black/African American and White parents with respect to both ratings of mean frequencies of problem behaviors and level of concern. Of interest, although there were no differences in the frequencies of problem behaviors, Black/African American parents were more likely to be concerned about their children's problem behaviors. This finding indicates that Black/African American families were using a lower threshold for concern.

At this point in time, very few psychological tests, scales, or interview assessments have been examined for cultural, racial, or ethnic appropriateness for even the largest racial/ethnic groups in the United States. This is particularly challenging for the clinician, who must struggle to make meaning from an individual profile. Researchers and test developers should be encouraged not only to increase diversity within samples (i.e., matching regional demographic characteristics) but to gather adequately large samples to permit cross-group validation.

Interplay within and across Multiple Domains and Contexts

The following example illuminates the challenges of integrating information across domains of functioning and contextual levels. A Latina girl is referred based on a concern that she has significant attentional and hyperactivity problems. During a developmental interview, the examiner learns that there have been several significant recent stressors in the family (e.g., death of a grandparent who was a caretaker, move secondary to mother's promotion) and a chronic childhood illness (asthma). In addition, the child is reported to show symptoms of hyperactivity at home but not in school and is observed to be quite active and inattentive during the evaluation. Upon formal assessment, the child has an unremarkable cognitive and academic profile with average scores in all domains assessed. In contrast,

based on both parent and teacher reports, her social and adaptive skills appear to be below average. The parents report that difficulties in these areas of functioning represent a change. In her previous school and community, which were more culturally diverse, she had many friends and was engaged in many activities.

This scenario highlights the complexities of children's lives in our modern society. Children struggle with loss, family and community transitions, and the need to situate one's ethnic/racial identity within relationships across multiple contextual levels. Moreover, a child's or adolescent's profile of strengths and weaknesses across developmental domains transacts with contextual risk and protective factors to shape developmental trajectories.

In this clinical scenario, the question of attentional difficulties and impulsivity might best be addressed through a formulation that takes into account both individual and ecological factors. Given the occurrence of significant recent life stressors, the lack of neurocognitive indicators of attentional deficits such as a relative weakness in executive functions or working memory and the lack of pervasiveness in symptom presentation across contexts or time, a prudent approach might entail the following: (1) Identify the psychopathological risks, such as ADHD and/or anxiety; (2) adopt an intervention approach that first addresses the individual and contextual risks; and (3) promote follow-up that will allow for further clarification of the diagnostic picture. Steps might be taken to help the child cope with the recent transitions and aid in the development of new friendships. Following a period of transition and, ideally, social reengagement, the evaluator might examine whether the attentional and impulsivity problems persist in the home or have generalized to other settings. By examining multiple levels of the child's ecology (e.g., recent family stressors, community transitions, and threats to cultural identity), it is possible to develop a more comprehensive understanding of the child's current presentation and to develop an intervention approach that recognizes the complexities of the child's day-to-day life situation.

This example highlights some aspects of interplay across both domains and contexts. There are several features of the interplay within and among domains and contexts that often arise when conducting assessments of children and adolescents. Directly relevant to interplay at the multidimensional level of the Comprehensive Psychological Assessment model is that despite the desire of test developers to create pure measures of particular constructs, this ideal is rarely, if ever, realized. Because a problem or strength in one domain may influence observed performance on a test purported to assess a separate domain, it is very important

to understand the different skills that specific tests require and to look across tests to determine the child's or adolescent's profile of abilities. Related to this measurement problem is the reality that a deficit, delay, or diagnosis in one domain of functioning places children at higher risk in other domains of functioning, independent of assessment method. For example, children with specific language disorders, reading disabilities, and cognitive impairments are all at higher risk for a mental health disturbance (Beitchman, Wilson, & Johnson, 2001; Benasich, Curtiss, & Tallal, 1993). Reciprocally, children who have sought treatment for psychiatric disorders evidence increased rates of learning and language difficulties (Jenkins, Bax, & Hart, 1980). For some children, a primary language problem may lead to social withdrawal, and social withdrawal diminishes opportunities for acquiring and enhancing social skills; thus, a negative feedback cycle can be set into motion. The evaluator's awareness of commonly occurring problems across domains influences decisions regarding the identification of appropriate domains of assessment.

Interplay across nested contexts is similar to interplay across observed domains with respect to impact on individual functioning. Just as risk in one domain places children at risk in other domains of functioning, risks at one contextual level are likely to co-occur with risks at other contextual levels. Given the complexity of assessing contextual factors and the high likelihood of co-occurrence of risk factors across different levels of the child's or adolescent's environment, many researchers advocate the use of cumulative risk models and measures (e.g., Sameroff et al., 2004). In these cumulative risk factor models, demographic risk factors such as poverty status, single-parent household, low maternal education, unemployment, and child sex are included along with family factors such as insensitive and/or harsh parenting style, marital discord, and exposure to domestic violence and community factors such as exposure to violence and lack of neighborhood social cohesion. Interplay across nested contexts and domains can take myriad forms. In clinical settings, we cannot reliably determine whether influences at the domain and contextual levels are additive, moderating, mediating, or transactional. However, consideration of conceptual and statistical models can aid in understanding reciprocal influences between the individual's functioning and the contexts of his or her daily life. It can be particularly helpful to consider these models when integrating information about previous functioning or when reevaluating a child or adolescent. Recognizing the reality constraints in the child's and family's ecology should moderate the recommendations that are offered to families. For example, it is within the role of the clinical

evaluator to help a family understand the systems that may aid the child's developmental progress and to assist parents in advocating for the child within these systems.

TEST CONSTRUCTION AND SCALING ISSUES

A developmentally informed comprehensive perspective on psychological assessment can be achieved only with a basic understanding of psychometric and methodological issues. We begin our discussion of these issues with a focus on standardization, reliability, and validity. Although these concepts are frequently given only passing attention in clinical practice and research, conceptual issues such as item scaling and a test's factor structure are critical considerations for assessing the development of an individual or group. This section briefly reviews some of the influences of psychometric issues on measures that try to describe developmental processes.

Item Selection

One psychometric issue in test construction that will influence a test's sensitivity to developmental change is item selection, often discussed under the rubric of content validity. The seemingly simple act of developing or choosing a specific item (or a specific behavior, if using a behavioral approach to assessment) for a specific measure depends on our understanding of the normal progression and unfolding of abilities as well as the appropriateness of particular items for describing phenomenology at specific ages and stages of development. Items are typically chosen and retained on tests based on their content, structure, and statistical characteristics. An item's content represents a sample of the measured domain or function; its structure represents the item's format. For example, if one were developing a vocabulary measure, content could be varied by changing the words included in the item, and structure, by changing the response required by the individual (e.g., seeing if the child touches the object that is named, asking for a definition of the word, requesting that the child or adolescent point to a picture within an array of pictures that best represents the word, asking the child or adolescent to use the word in a sentence). Critical developmental considerations are involved in decisions regarding content. For instance, the population of words that can be used across development changes significantly, from few if any during early infancy, to thousands, if not hundreds of thousands, during adolescence and adulthood. To best represent and assess an individual's vocabulary, an understanding of the

normal developmental progression of language abilities is necessary. In addition, developmental considerations are inherent in choosing the structure for an item. Younger children have been shown to have a more extensive receptive vocabulary than expressive (or written) vocabulary. Within the expressive domain, an item requiring a young child to label an object or picture of a familiar object would yield a very different view of vocabulary than an item requiring a verbal definition or use in a sentence. This language example, like examples that could have been drawn from multiple domains, has obvious developmental implications. Once an item pool is selected that varies in both content and structure, sophisticated statistical item-scaling methods can be employed to determine the difficulty level of items and to assign developmentally appropriate ordering of scale items (e.g., Rasch scaling method; Woodcock & Dahl, 1971).

Some theoretical statistical models are conceptually useful for guiding the construction of developmentally appropriate items and measures. For example, based on its underlying assumptions (i.e., item parameter invariance across groups), item response or latent trait theory suggests that a general measure can be developed with scaling that can be compared across subjects of greatly differing abilities. In addition, this model suggests that one can use completely different groups of items for different groups of participants and still compare their results. Given these assumptions, one could choose different sets of developmentally appropriate items for groups of participants who are at very different developmental stages, develop measures from each set of items, and still be able to compare the actual scores obtained across the groups or within a group across time. Although this item development model is considered to be very strong in theory, there are few actual examples of its use outside of the achievement or adaptive behavior domains. Even within the achievement area, the use of sets of anchor or calibration items has been required to help this model work. This strategy has significant advantages given recent developments in longitudinal modeling of trajectories (Sayer & Cumsille, 2001).

The statistical properties of each item within a particular measure also have to be considered in the developmental context. One of the most difficult measurement problems in assessing developmental functions occurs when a distribution of scores is nonnormal, especially when there is a positive or negative skew. Most often, nonnormal distribution of scores occurs with those items that fall at either end of the continuum of difficulty. When a large portion of the chosen items is either too easy or too difficult for a specific developmental level, there will be little variability in

performance on those items. Items that are too easy will result in many individuals obtaining the highest scores possible on the measure (ceiling effect), and items that are too difficult will result in a majority of individuals obtaining very low scores (floor effect). This problem is easily illustrated if one considers what would happen if a majority of the items on a reading test were at the fifth-grade reading level and it was given either to a group of first-graders (floor effect) or 12th graders (ceiling effect). In either situation, it is not possible to accurately scale or measure an individual's true abilities because they fall within the tail end of either distribution. It is also extremely difficult to examine change, over time, in individuals who are already scoring at the ceiling of a measure, or who may be limited to scoring at the floor end of a measure. Such developmentally insensitive measures also severely limit one's ability to compare relations between constructs. In part, this is due to the statistical restrictions in variance that ceiling and floor effects cause. Restriction in variance (i.e., all respondents obtaining approximately the same score) will always limit the amount of covariance possible between measures (i.e., the ability of scores on one measure to predict scores on another measure, or on the same measure at a future point in time).

Standardization

The traditional standardization approach is often developmental, in that norms are developed to compare individuals to their age-based peer group. In many ways, the concept of norms is central to a developmental perspective for assessment. Although traditionally a norm is considered to represent the average test performance of a standardization sample, it is very easy to consider a norm as representing the average, median, or modal performance of a particular developmental level or stage. In a majority of the tests available, the most typical way to operationalize development has been based on chronological age, partly because of ease of use. A developmental level or stage, though, may be defined based on an individual's ability to perform a particular cognitive task (i.e., object permanence). Regardless of the dimension chosen as an index of developmental level, and in order to obtain a norm for reference purposes, a decision on where to partition the dimension has to be made. For example, with respect to the Vineland Adaptive Behavior Scales, when developing special population norms for Autism, a decision was made to divide individuals who were mute from those who had any expressive language (Carter et al., 1998).

Normative data also have to be considered within the cultural, historical, and societal frameworks in which they are developed. There has been considerable discussion regarding the concept of cohort effects in developmental research. In some domains, the historical events of the nation (i.e., the Great Depression, World War II) or of a local community (i.e., tsunami, casinos) may have very strong effects on an individual's developmental progression in a number of domains. Norms developed in such situations may not be adequate representations for a different cohort that has not had similar environmental/historical/cultural experiences. For this reason, periodic restandardization of measures is very important.

Reliability

There are many different types of reliability estimates that are critical to consider in a developmentally informed manner in the Comprehensive Psychological Assessment model. One of the first reliability coefficients typically evaluated when reviewing a particular test or scale is test-retest reliability. The test-retest reliability coefficient is a direct examination of change over a short period in development. Typically, one would test a group of participants at one point in time and then again 2 weeks to 2 months later. In a developmental framework, even the shorter time frame of 2 weeks may be a time period in which the features of development being assessed undergo change. For example, a 2-week test-retest period for a measure designed to assess the first few months of infancy may be too long, as 2 weeks in a 1-month-old infant's lifetime represents a large portion of the infant's life and a period of rapid change in abilities. In contrast, a 2-week period in the life of a 15-year-old constitutes a smaller percentage of development and may represent a period in which little change is occurring. This issue is somewhat similar to the problem of comparing age- or grade-equivalent scores, as the likelihood of high concordance across age and grade standard scores varies based on whether a child is young for grade (e.g., has skipped a grade), old for grade (e.g., started kindergarten at age 7), or in the expected grade for age. Specifically, there may be a range of 4 years within a given classroom, with children between the ages of 7 and 10 years all in the third grade. Grade equivalents take into consideration that the older third-graders have not been exposed to academic material beyond the third-grade level, and therefore it is unlikely that they will have mastered this material. Thus, if academic achievement is comparable for the 7- and 10-year-old third-graders, they will achieve comparable scores using norms based on grade. In contrast, standard scores

will be quite different if norms based on age are utilized, with the 7-year-old appearing much more competent than the 10-year-old. Given that a test-retest reliability coefficient is designed to assess the consistency of a measure and is dependent on the stability of the assessed behavior, one has to consider that it may also include some variance caused by true individual changes that occur during certain periods of development.

The reliability of measurement is also important for comparing scores across different measures. When comparing the scores from two different measures, a statistically significant difference is based on the standard error of the difference scores, which is calculated using the reliability coefficients of each measure. The lower the reliability, the greater the score difference required before one is secure in deciding that there is a significant discrepancy. Individuals at different developmental levels may require larger or smaller score differences because of differences in the reliability of the measures used at different levels. Given that younger children may also have a more limited range of scores on such a scale, especially when one considers their limited raw score performances, it may be psychometrically less common for them to exhibit such a magnitude of differences between the measures. Large standard errors of measurement, reflecting low reliability coefficients, are of particular concern if there are floor or ceiling effects limiting the variability of individual performance on the measures involved. This is most likely to occur at the lowest and highest ages for which a measure is designed to assess. However, it is unlikely that large standard errors of measurement can be obtained when there are floor or ceiling effects because range restriction in the scores obtained will artificially inflate the reliability coefficients. When reliability coefficients are inflated due to limited variance, the standard error of the differences is artificially decreased, and interpretations may be wrongly made regarding differences between measures when this might not be the case.

Validity

The construct validity of a measure also may be affected by developmental processes. Although many measures are analyzed by using factor analytic methods to confirm their underlying traits or constructs, very few are analyzed within a developmental framework. When developing a measure that is designed for longitudinal use, it is extremely valuable to test whether the latent structure of the measure is comparable across developmental periods or ages (e.g., Carter et al., 2003). Such an analytic plan is also

required to describe the changing patterns of the traits or constructs over development. Rather than making an assumption that a particular measure has the same structure, or even measures the same traits/constructs over development, it is necessary to formally evaluate these properties.

In addition to a measure's construct validity, there are developmental considerations regarding its predictive validity. Most measures are more predictive over shorter time periods than over longer periods, but there may be exceptions (e.g., sleeper effects). Measures that have inadequate validity with respect to psychometric criteria will artificially limit our understanding of both the underlying dimensions and the processes of change that are occurring and/or lead to mistaken conclusions about functioning at one time point and over time. Therefore, such basic psychometric considerations are central to any strong developmental model for assessment.

Sensitivity-Specificity

Although a test or measure may be a reliable and valid measure of an underlying construct or behavior, there is still an issue of how useful it might be for a given diagnostic or classification purpose (e.g., meets criteria for Oppositional Defiant Disorder, is peer-rejected, has a learning disability). Of most concern within this realm is the problem of misclassification and its impact on the person being classified. The measures of sensitivity (proportion of a sample found to fall within a diagnostic category) and specificity (proportion of a sample not falling within a diagnostic category) help to determine how well any test can be used for a specific diagnostic purpose. In addition, the measures of predictive value of a positive result and predictive value of a negative result provide information regarding how useful a particular test is for a specific population being classified. These latter concepts have significant applicability in evaluating a specific test for use with various populations during different developmental periods. One should not expect any one test to have stable sensitivity and specificity for a particular diagnostic decision across the developmental spectrum. For example, there are many specific diagnostic conditions (e.g., dementia, depression, speech disorders) that might have different base rates at different ages. If we have a test that has very good sensitivity and specificity (e.g., 80% to 90%) at one developmental level, and try to use it with another developmental group that has a different base rate of the disorder, then the sensitivity and specificity could change significantly and the test may not be adequate for the purpose at

hand, even though its reliability and psychometric properties remain strong and stable.

METHODS

In approaching specific assessment strategies, whether for clinical or research applications, a common starting point is to review available tests or instruments. As noted earlier, we advocate an alternative approach, which is to begin by determining the domains and constructs within domains most relevant to the questions being asked. Once domains and constructs are determined, it is important to select the methods that will be most informative. The methods may include standardized tests, which represent the most structured of available procedures, but other available methods should also be considered. In isolation, standardized tests are rarely sufficient to answer the questions that researchers and clinicians attempt to answer. For example, even when evaluating intelligence, the obtained scores on a particular IQ test can be interpreted only in the context of observational and situational data (e.g., compliance, attention, motivation). The Cross-Battery approach (Flanagan & Ortiz, 2001; McGrew & Flanagan, 1998) offers an excellent guide for identifying unique and shared abilities across cognitive subtests of multiple instruments. To the extent that a multitrait, multi-informant, multimethod matrix can be developed to address the questions of interest, multiple sources of method error variance can be examined and a clearer understanding of the constructs under consideration will emerge (Campbell & Fiske, 1959).

For heuristic purposes, we have chosen to discuss reporting sources and specific types of tools for gathering information that are particularly relevant to a Comprehensive Psychological Assessment approach and that demonstrate how the use of multiple methods enriches the validity and generalizability of the outcome.

Reporting Source

The routine evaluation of individuals in isolation is artificial and provides only a partial picture of current functioning. Typically, multiple sources of information can be obtained about multiple domains of functioning as well as contextual factors. For children and adolescents, examples include contacting teachers and caregivers to obtain additional information in the domains of academic, cognitive, social-emotional, and adaptive functioning as well as reviewing school records for academic achievement. For adults, examples include interviewing spouses and family

members to obtain relevant information in the domains of personality and social and adaptive functioning as well as medical chart review as an adjunct to a neuropsychological evaluation. Because multiple informants often provide conflicting information, their inclusion often complicates data integration. However, conflicting data are often informative and contribute an added dimension to the assessment, especially in terms of understanding the systems in which the individual functions. As informants may have access to different samples of behavior in multiple settings, conflicting information may reflect true variability in current functioning. On the other hand, conflicting information may be a function of observer or interviewer biases. When the informant will be involved in implementing recommendations, having some knowledge of any potential biases may be extremely useful. It should also be acknowledged that in some situations, the use of other informants is the only way to obtain information about a relevant domain, either because the behaviors of interest have such a low base rate of occurrence and are unlikely to occur in the testing situation or because the individual is unable to provide the information (e.g., coma, psychosis, dementia, severe retardation, infancy). When considering the inclusion of multiple informants, care must be taken to protect the individual's confidentiality. Informed consent must be secured from the individual or legal guardian prior to obtaining information from outside sources.

Interviews, Rating Scales, and Questionnaires

In the past, interviews were more commonly employed in clinical assessments, and rating scales and questionnaires more commonly employed in research applications. However, as more questionnaires and rating scales become available with appropriate normative information, and as clinical interview methods are standardized, the versatility of these methods increases. For each method, the adequacy of the sample on which normative data are based should be evaluated carefully along a number of dimensions: sample size, representativeness of age, sex, socioeconomic status, ethnicity, and size of community. For example, when evaluating an individual to rule out a diagnosis of mental retardation, both intelligence and adaptive behavior must be assessed with instruments that have been normed on a large sample that is representative of the total population. However, it may also be important to determine how a mentally retarded individual is functioning relative to other individuals with the same diagnosis. Therefore, the existence of additional norms, including a representative sample of in-

dividuals who are mentally retarded, might influence the selection of a specific instrument for this purpose.

A central concern when employing interviews, rating scales, or questionnaires is the potential bias of the informant, typically discussed in terms of response styles. For example, an informant may attempt to present in a socially conventional manner or in a negative light to gain access to treatment or services. Some scales have incorporated social desirability indices or veracity scales which can detect such response biases and provide correction formulas (e.g., MMPI-2: Graham, 1991). A second concern is the reliability of the instrument. For both rating scales and interviews, the more structured the format, the easier it is to obtain adequate test-retest and interrater reliability coefficients. Similarly, the lower the inference level required to make ratings (either for the informant or the interviewer), the greater the probability that adequate reliability can be obtained.

Observational Methods

Consistent with interview, rating scale, and questionnaire data, observational methods vary along a continuum of structure and the level of inference required to evaluate the constructs of interest. In addition, observational data add the dimension of time, and decisions must be made regarding the time frame of the analysis (e.g., continuous versus time or event sampling). The unit of analysis in terms of a microanalytic or macroanalytic focus must also be considered. Such decisions will be driven by the constructs under study. When conducting evaluations, we continually make observations that guide our subsequent behavior and decision-making processes. Research employing observational methods in areas such as interpersonal processes and play have made significant contributions to our knowledge base. However, few structured observational methods have been developed and standardized sufficiently to permit their use in clinical applications. As previously mentioned, one exception is the Autism Diagnostic Observational Schedule (ADOS; Lord et al., 2000). The ADOS is a semi-structured, interactive observational tool designed to assess social and communicative functioning in individuals who may have an Autism spectrum disorder. The assessment involves a variety of social occasions and “presses” designed to elicit behaviors relevant to a diagnosis of Autism. A standardized diagnostic algorithm can be computed, composed of a subset of rated social and communicative behaviors, and consistent with Autism criteria in the *Diagnostic and Statistical Manual of Mental Disorders IV* (American Psychiatric Association, 1994) and the *Inter-*

national Classification of Diseases 10 (World Health Organization, 1992). The use of presses to elicit behaviors that might not be commonly observed in an evaluation session is one of the innovative aspects of the ADOS. Recently, Wakschlag et al. (2002, in press), using the ADOS as a model, developed an observational tool to aid in the diagnosis of preschoolers with disruptive behavior disorders. The child is observed in three contexts that vary the degree of external regulatory support that is afforded, including interactions with the examiner and with a parent. Both problem behaviors and competencies are coded using a coding scheme that attends not only to the frequency of behaviors salient for a diagnosis of disruptive behavior but also for the quality of these behaviors.

Projective Methods

Freud introduced the term “projection” in 1894 and explained it as a strategy for assigning attributions (Exner, 1991). Since the introduction of projective techniques in the United States in the 1930s, their use has been highly controversial. The basic assumption underlying the use of projective techniques is that an individual’s responses to an ambiguous stimulus or set of stimuli reveal something about the way he or she perceives, interprets, and organizes the information presented (Maloney & Ward, 1976). A further assumption is that these perceptions, interpretations, and organizational strategies inform the examiner about personality, unconscious processes, psychopathology, and reality testing. A primary feature of all projective techniques is that they involve a relatively unstructured demand or task. Typically, the examinee is not aware of how the test will be interpreted. Controversy has centered on issues of reliability and validity and has led to attempts to standardize administration, scoring, and interpretation by developing methods of quantifying ratings of responses. Over the years, many systems have been proposed for one of the most widely used projective techniques, the Rorschach Inkblot task. For example, systems have been developed by Beck (1944), Klopfer & Donaldson (1962), and Rappaport, Gill, and Schaffer (1968). Exner has built on previous methods to develop a comprehensive system for the Rorschach Inkblot task that includes normative data. Other currently employed projective methods include sentence completion tasks, figure drawings, and storytelling tasks.

Despite the controversy, projective techniques continue to be employed as a primary means of assessing and understanding personality and emotional development in school-age children and adults. Play interview techniques are also employed with preschool-age children, making use of the

same set of projective assumptions to assess social-emotional functioning. The MacArthur Network Collaborative Study of children's use of narratives, directed by Robert Emde, built on sentence completion tasks and play interviews to develop the MacArthur Story Stem Battery (Emde, Wolf, & Oppenheim, 2003). This task involves the presentation of structured story stems that are organized around relevant themes (e.g., attachment, separation, misbehavior) accompanied by toy props. This kind of methodology presents an opportunity for developing a quantifiable normed projective instrument for use with preschoolers.

IMPLEMENTING THE MODEL: HYPOTHESIS-DRIVEN ASSESSMENT

The terms comprehensive and developmental, emphasized throughout this chapter, must remain salient at each phase of implementation. To recapitulate, by *comprehensive*, we refer to obtaining data about the individual's functioning across a broad range of domains (i.e., cognition, language, social-emotional and personality, adaptive behavior, and academic/occupational achievement). The assessment should address not only functioning within domains, but also reciprocal influences between domains. By *developmental*, we refer to the notion that an individual's functioning in these domains can be understood only in the context of normative expectations for performance during a given developmental period (Cicchetti, 1984).

Goals of the Assessment

Assessment is aimed at painting a comprehensive picture of an individual's functioning within and across domains as it relates to the level of development. This model of Comprehensive Psychological Assessment is applicable to the evaluation of individuals and groups for research or for clinical purposes. In each case, one must establish (1) the goals of the assessment; (2) the relevant domains of assessment; (3) appropriate instruments; (4) the relations among selected instruments; (5) contextual factors that influence performance on these instruments; (6) a synthesis and interpretation of the obtained information, which provides a parsimonious understanding of the individual's current functioning; and (7) communication of this understanding of the individual's functioning to relevant levels of the developmental system, along with recommendations for any indicated interventions. When the model is implemented, these component parts are not necessarily discrete or sequential. Rather, the examiner engages in an ongoing inter-

active feedback loop among all of these component parts at each phase of the evaluation.

Because of the multifactorial characteristics of any single measure, it is critical to use multiple measures and to have a good understanding of unique and shared abilities (i.e., latent constructs) that will contribute to the score obtained on a specific instrument. At the individual level, the use of multiple measures permits an analysis of patterns of convergence and divergence across instruments. Once measurement error is minimized, it is possible to determine patterns of relative strengths and weaknesses across multiple domains of development. Thus, the use of multiple instruments heightens one's confidence in a given finding because the error contribution from a single measurement source is minimized. At the nomothetic level, cluster and factor analytic approaches have been employed to identify patterns of functioning across relevant developmental domains that can lead to the successful classification of discrete subtypes or groups of individuals. An example of employment of this approach can be seen in clinical research that seeks to identify specific subtypes of learning disabilities (Fletcher, 1985; Morris, Blashfield, & Satz, 1986; Rourke, 1985).

Hypothesis-Driven Assessment Approach

In clinical situations, we endorse utilizing a strategy of hypothesis-driven assessment. Hypothesis-driven assessment refers to a process in which each step in the evaluation is guided by hypotheses generated from currently available information. A dynamic process is involved: The available information changes throughout the course of the assessment. A comparison between this approach and a standard comprehensive battery is analogous to the distinction between theory-driven research and shotgun research. The hypothesis-driven approach has a higher probability of hitting the relevant target in terms of obtaining information that is truly explanatory in the individual case. Kaufman (1983, 1994; Flanagan & Kaufman, 2004) has written widely about this approach to assessment. His major focus has been on intelligence and the most widely used tests of intelligence. In this model, we advocate the application of this approach across the spectrum of assessed domains. At points in the life span when developmental changes may play a larger role, it is critical to apply a developmentally informed perspective to hypothesis generation, instrument selection, and inferences derived from observational and quantitative data.

When presented with the task of selecting the initial goals of the assessment and choosing the domains that will

be emphasized, the first piece of information that is available is typically the referral question. Based on the referral question, initial hypotheses are generated. These initial hypotheses guide the identification of relevant domains to assess, which in turn guide the selection of available instruments. Ideally, each domain of assessment relevant to the referral question will be addressed in a preliminary way in the first session with the individual. Based on the preliminary data, the next step of the assessment is designed. The preliminary data may support or disconfirm the initial hypotheses or may suggest additional hypotheses meriting further exploration. This approach is in marked contrast to administering a standard, lengthy battery to all individuals. A practical implication of this approach is that multiple assessment sessions over time are preferred to one or two extended sessions.

The use of multiple sessions provides an opportunity to score and evaluate information, refine hypotheses, and customize selection of instruments to elucidate strengths and weaknesses of the individual being evaluated. Intersession variability has often been considered a component of unexplained or error variance from a test-and-measurement perspective. However, when dealing with an individual case, this variability may be quite informative. Understanding the immediate assessment situation as a context that can exert influence on the individual's functioning can be quite informative. The immediate evaluation setting refers to situational factors in the testing, such as the physical environment of the testing room, the gender and/or race of the examiner, interpersonal style and/or comfort level of the examiner, order and number of tasks presented, the child's or adolescent's physical health, and the child's or adolescent's understanding of the purpose of the testing. The examiner should be attentive to the child's or adolescent's unique responses and interpretations of the testing experience and their impact on the examiner's behaviors. Thus, the use of multiple sessions often provides a more reliable and accurate estimate of the individual's behavior. This is especially important when evaluating children, whose behavior is likely to change and be more variable over time.

Appropriate and Inappropriate Referral and Research Questions

To implement this approach to assessment successfully, referral questions should be specific and should be based on information about the individual in multiple settings of the developmental system. Specific questions facilitate the generation of preliminary hypotheses to be pursued during the assessment. This is true for research studies that inves-

tigate groups of individuals and make clinical evaluations of individuals. For example, a global request regarding an individual's IQ score when there is a nonstated concern about language functioning may interfere with the selection of the most appropriate instruments for evaluating intelligence and language in this individual, because different IQ tests vary in their emphasis on verbal functioning in the determination of global intelligence. Similarly, when conducting research, it is important to determine the specific construct being measured and the interaction of the construct with the dependent variables under study. For example, if the interest is in evaluating children diagnosed with ADHD and non-ADHD children on listening vocabulary, the selection of a cognitive test must take into consideration how much the instrument is influenced by the attentional behavior associated with the diagnosis of ADHD. Thus, if an instrument is selected and used in isolation (e.g., a test of listening vocabulary such as the Peabody Picture Vocabulary Test, Revised; Dunn & Dunn, 1981), it is critical to recognize all the known influences that may contribute to the obtained scores. Attentional difficulties may well compromise performance on this task, such that presumed group differences in listening vocabulary are more parsimoniously explained in terms of differences in attentional ability.

Steps to Interpretation

The steps to interpretation that we describe assume that multiple measures have been employed to evaluate multiple domains of functioning. The initial phase of interpretation involves a systematic analysis of each of the individual measures administered. Because many of the measures comprise multiple subtests, this process involves identifying the unique and shared abilities assessed within the subtests that compose each of the individual tests administered. Consistent with the approach described by Kaufman (1990) for the Wechsler scales and by Sparrow et al. (1984) for the Vineland Adaptive Behavior Scales, we advocate beginning the analysis of individual tests by analyzing the most global and psychometrically robust level (e.g., Full-Scale IQ [FSIQ] or Adaptive Behavior Composite). In this first step, it is essential to recognize the contribution of the variability in the subtests or subdomains underlying the global scores (e.g., statistically and/or clinically significant Verbal IQ [VIQ] and Performance IQ [PIQ] discrepancies, or communication, socialization, daily living skills, and/or motor discrepancies).

Often, a global score may misrepresent an individual's functioning because of the variability of the component

scores. Subsequently, we proceed from the most molar (i.e., global score) to the next most robust level of analysis, proceeding systematically to the most molecular level of analysis (i.e., an individual item within a particular subtest). To guide this exploration and prevent interpretations of differences that may be a function of chance, it is critical to use available psychometric data. For example, prior to interpreting a profile of strengths and weaknesses based on a pattern of subtest scores, one must account for the fact that there are differences in the reliabilities of each of the subtests that compose various scales. This is accomplished by determining whether observed subtest scatter is meaningful. In both research and clinical settings, the evaluator must address both statistical and clinical significance. The latter case involves the clinician's examining the normative data to determine whether a particular degree of variability is markedly unusual. A common fallacy in test interpretation is that statistical significance is viewed as clinically meaningful, even when 40% of the population may evidence a statistically significant level of variability.

A further caution at the level of individual test analysis is to employ developmental knowledge to inform the interpretation of particular patterns of subtest variability. Specifically, one must be sensitive to the fact that individual subtests on a given instrument may purportedly reflect the *same* underlying abilities at *different* developmental levels but be assessed with tasks that, at least on the surface, appear quite distinct. This type of discontinuity arises on the Stanford Binet Intelligence Scales, fifth edition (SB5; Roid, 2003) when assessing verbal reasoning. At Verbal Level 2, the child is asked to describe the cause and effect of events depicted in pictures, whereas at Verbal 3 the child must sort plastic chips with pictures on them into meaningful categories. Alternatively, individual subtests may assess *different* underlying abilities at different developmental levels but make use of tasks that on the surface appear similar. For example, on the Vocabulary subtests of the Weschler Preschool and Primary Scale of Intelligence, third edition (WPPSI-III; Wechsler, 2002) and the Weschler Intelligence Scale for Children, fourth edition (WISC-IV; Wechsler, 2003), the child initially names pictures, and then must make a shift to generating definitions, a qualitative change in task demands.

Employing a Comprehensive Psychological Assessment approach increases the level of interpretive complexity, in part because of a lack of empirical guidelines for synthesizing information across different tests. Thus, when there is variability in the information obtained across two or more tests, there are no empirical data to guide the deter-

mination of whether the variability is statistically or clinically meaningful. The interpreter must rely on his or her knowledge of the specific task demands of and latent abilities assessed by the different tests. This knowledge must be complemented by a grasp of the contextual influences present when each of the tasks was administered. To help clarify discrepant information about a specific ability, it is often valuable to administer additional measures that illuminate the specific ability with greater precision.

The increase in journals dedicated to research on measurement and assessment should provide an additional source of guidance on interpreting test information. For example, studies employing comprehensive assessment approaches with large numbers of subjects provide important information about patterns of functioning evidenced by individuals with specific disorders, such as learning disabilities or neurological dysfunction (see Kaufman, 1994). Contextual factors to be considered in evaluating performance on multiple measures include not only influences evident in the testing situation, but also available background information and a profile of the individual's functioning within the developmental systems levels. For example, when evaluating an individual with suspected depression, it is critical to consider the salient developmental challenges in which the individual is engaged (e.g., peer relations and individuation in adolescence), developmentally appropriate modes of expression (e.g., capacities for affective expression, attention, behavioral control), and domains of functioning known to influence the onset and maintenance of depression (e.g., social support, life events).

Once a parsimonious understanding of the individual's functioning across the relevant domains is achieved and appropriate recommendations are determined, it is critical to communicate this information to the pertinent individuals in the applicable levels of the individual's developmental system. Often, an exquisite evaluation is conducted, resulting in interpretations and recommendations that offer great potential for assistance to the individual, but the results are communicated inadequately or in a manner that interferes with the implementation of the recommendations. Even when the individual receiving the recommendation agrees with the evaluator, failure to implement recommendations may occur because the recipient fails to understand the findings on which the recommendations are based. When an understanding of the relation of the findings to the recommendations is achieved, the intervenors can generalize the bases of the recommendations to new situations. A second difficulty emerges when the individual receiving the recommendations understands the findings and agrees with

the recommendations, but does not have the skills or knowledge to communicate the findings to the appropriate agents within the developmental systems levels in which the individual assessed will require intervention. Thus, it is incumbent on the evaluator to take the time to make certain that the pertinent individuals in the developmental systems levels understand the findings and the relation of the findings to the recommendations. In addition, more often than not, recipients of the information will require guidelines and support to ensure implementation of the recommendations they accept.

RECENT ADVANCES AND DIRECTIONS FOR FUTURE RESEARCH

Many of the directions for future research offered in the first edition of this volume a decade ago (Sparrow et al., 1995) are still relevant. It is our hope that by highlighting areas in which there have been advances that can be applied to the Comprehensive Psychological Assessment model as well as areas in which there is current momentum, we can generate directions for future research that have the potential for being realized in the next decade. In many respects, the assessment process is one that theorists, empiricists, and practitioners require to pursue individual and joint agendas aimed at understanding individual functioning within multilevel contexts throughout the course of development, as well as the identification of processes involved in normative and psychopathological development. The shared need for well-articulated assessment models, developmentally sensitive instrumentation, and rigorous approaches to the interpretation of findings should provide the impetus for future innovations.

In our Comprehensive Psychological Assessment model, we discuss the importance of understanding the interplay among multiple domains within the individual and multiple contextual levels as well as transactions between the individual and contextual levels. There have been many advances that facilitate the goal of understanding these complex systems: (1) refined characterization of specific domains of individual functioning and ecological levels that have led to improved instrumentation, (2) new statistical methods that allow for more sophisticated understanding of the psychometric properties of instruments and their applicability in different subpopulations, and (3) new integrative approaches to standardization that allow improved interpretation of findings across instruments and domains.

Researchers and clinicians have contributed to increasingly sophisticated conceptualizations of multiple domains of individual functioning such as cognition, language, academic skills, and socioemotional functioning as well as levels of the ecological system such as families and peers, institutions, communities, and culture. There has been a corresponding expansion of innovative methods for evaluating both individual functioning and multilevel, nested contexts. In terms of individual functioning, we have highlighted the advances made in areas such as cognition and acquisition of academic skills. For example, there are new standardized, norm-referenced measures available to assess attention and executive functions (e.g., D-KEFS: Delis et al., 2001; BRIEF-Preschool Version: Gioia et al., 2003; BRIEF: Gioia et al., 2000; NEPSY: Korkman et al., 1998) and underlying reading abilities (e.g., CTOPP: Wagner et al., 1999). Another area that has seen dramatic instrument development is the domain of social-emotional development and psychopathology focused on young children (Carter, Briggs-Gowan, & Davis, 2004; DelCarmen-Wiggins & Carter, 2004). Consistent with measures available for older children, the majority of new instruments involve problem/competence checklists and diagnostic interviews. However, other innovations are also evident in those structured observational systems that have been developed for use with specific populations (ADOS: Lord et al., 2000; DB-DOS: Wakschlag et al., 2002, in press).

With respect to nested ecologies, researchers have continued to systematically measure parent-child interactions and peer relationships. Newer developments have also arisen to meet the need to better characterize the quality of out-of-home environments such as day care, Head Start, and schools as well as the quality of caregiver-child relationships. Assessment of neighborhoods has also become possible with integration of observational, ethnographic, demographic, and self-report instruments (Leventhal & Brooks-Gunn, 2003). These measures are still predominantly being used for research purposes. However, as research increasingly incorporates hypotheses about the role of contextual levels on individual functioning and needs to make use of such measures, it is likely that additional progress in measurement development will be fostered, perhaps even with new applications fitting for clinical use.

Although these developments are encouraging, there are other arenas in which less progress has been made. In particular, in our previous chapter (Sparrow et al., 1995), we urged that enhanced conceptualization, methods, and measurement of cognition and adaptive functioning at the low end of the spectrum were needed. Because of the limited

number of appropriate items at the low end of many assessment instruments, floor effects limit our ability to generate a meaningful profile of strengths and weaknesses. These issues continue to be relevant at this point in time, and the paucity of sensitive, developmentally appropriate measures leads to circumscribed understanding of these individuals, their ecologies, and how best to address the needs of these individuals across the life span.

Statistical methods that inform developmentally sensitive psychometric analysis (e.g., Rasch scaling) as well as methods of multigroup modeling to examine structural invariance, or the comparability of factor structure, across age and cultural groups are currently in use to improve the development and limits of a wide range of instruments (Little, 1997). To the extent that investigators test for structural invariance across age groups it becomes possible to model development over time with greater confidence that the same latent constructs are being assessed at different time/age points. There has been concurrent progress in statistical methods that can be applied to understanding developmental trajectories (Collins & Sayer, 2001). Although expensive, we hope that in the next decade publishing companies might consider longitudinal norming of standardized measures so that empirical findings regarding stability and errors of measurement can inform our understanding of continuity and discontinuity at both the group and individual levels. At present, when an individual is assessed at multiple points in time, it is complicated to determine when scores reflect true developmental change in either a positive or negative direction and when, in contrast to reflecting true developmental change, an apparent change over time is actually a function of retest or practice effects or falls within the measurement error of the instrument.

Another development in the psychometric arena is the increasing number of test instruments that are being normed concurrently with instruments that assess a different domain of functioning. Recent examples are the conorming of the Wechsler Intelligence Scale for Children, third edition (WISC-III) and Wechsler Individual Achievement Test, second edition (WIAT-II) and of the Kaufman Assessment Battery for Children, second edition (KABC-II) with the Vineland Adaptive Behavior Scales, second edition (Vineland-II). We hope that this is a persistent trend because interpreting relative strengths and weaknesses across domains and characterizing profiles of functioning across domains is greatly facilitated by the use of a shared normative sample. That is, with conorming, one has greater confidence that a standard score of 100 on test A is comparable to a standard score of 100 on test B.

Related to the issue of conorming is improving the ability to engage in profile analysis; there have been recent efforts to develop new methods for aggregating data from multiple informants and methods that go beyond shared variance approaches and take into consideration the value of different measures for obtaining information about children in different contexts (Kraemer et al., 2003).

CONCLUSION

There is much to be enthusiastic about in the field of assessment and measurement, with the development of new measures that have stronger conceptual and psychometric properties, sophisticated statistical methods, and empirically informed approaches for integrating data across methods, informants, and time. Most researchers and clinicians have an implicit approach to assessment that guides their work, but there are few arenas in which explicit examination of the underpinnings and process of assessment approaches are examined. We have found that the process of articulating a working model or conceptual framework for Comprehensive Psychological Assessment facilitates a more systematic approach to measurement selection, data collection, and interpretation in both clinical and research settings. Just as the tenets of developmental psychopathology have influenced the Comprehensive Psychological Assessment model presented in this chapter, it is likely that advances in the field of assessment will contribute to a richer understanding of developmental psychopathology. Ultimately, pursuit of a multidimensional, multilevel, and dynamic perspective on individual functioning should result in increased knowledge about development in normative and psychopathological populations as well as enhance the success of intervention efforts that promote mental health and well-being.

PATHWAYS AS A FRAMEWORK FOR DEVELOPMENTAL PROCESSES

It is a feature of an evolving language, that groups—we scientists among them—take an everyday word, preferably one with exploitable connotations, and subvert its meaning to serve a rather different purpose. For scientists, this achieves certain short-term gains. First, what is thought to be a new concept can be introduced by the use of familiar words, helping in the process of getting the idea understood and accepted. Second, the words are rarely casually chosen, but instead have some meaning in everyday language

that shares something with their new intended use. Analogy has long been recognized as an important means by which new scientific theory becomes accepted (Feyerabend, 1975). In understanding something new, it helps to think in terms of something that we think we already understand. Explicit analogy is, however, surprisingly rare. Explicit analogy is often too stark, the shortcomings too self-evident, and the possible similarities and differences too numerous. Instead, we pick these everyday words and use them metaphorically. Metaphors achieve our immediate aim of giving an impression of the concept we are trying to communicate, but seem to do this without raising critical

thought. However, in the longer run, such lack of criticism and resulting imprecision can allow quite different and inconsistent understandings to coexist.

The use of the term “pathway” to describe aspects of development from childhood to adulthood has been one such all too alluring metaphor. It conjures up images of pathways through a landscape of life’s trials and tribulations, and implies, without actually saying so, that what we are about as scientists shares much with a distinguished literary tradition. We are like Dickens, except he lacked our theoretical and statistical insight and expertise! However, as we should expect, pathway has been seldom defined, and indeed it is used in several rather different ways. In this chapter, the different meanings of the term are reviewed and illustrated with examples, before going on to a more detailed consideration of the application of a pathways perspective in developmental psychopathology.

We start with a review of the possible features implied by the terms path and pathway and their translation into the understanding of development and psychopathology.

A PATHWAY AS PROTOTYPE OR IDEAL TYPE

The concept of a pathway has proved widely useful in the biological sciences, specifically in relation to development and psychopathology. In common with other terms that allow individuals to be classified, pathways can be proposed as either prototypes or ideal types. Both are selective of the features of reality that are given emphasis; both recognize fuzziness, and both attempt to overcome this vagueness by defining attributes in a clear and precise way. Moreover, both confront individual variability by recognizing individuals who more or less conform to the type. However, ideal types are a thought construct that postulates connections that provide a conceptual unity. Ideal types are concerned with empirical analysis to discover new or better ways of conceptualizing patients and their disorders. By contrast, a prototype consists of a list of attributes and is more concerned with explicating the meaning of a word as used. In this chapter, we are concerned almost exclusively with pathways as an ideal type. Whether developmental pathways are proposed as empirically identifiable constructs or as thought constructs only is less clear.

ELABORATING THE METAPHOR

The developmental pathway is a remarkably productive metaphor. However, its status is not yet clear. It is undoubt-

edly already a useful summary term in the field of development and psychopathology, and findings are often reported in terms of pathways. However, it is not clear whether the concept has yet claimed a place in shaping research questions. The answer in most cases is probably no because it is uncommon for researchers to report that their study questions and designs were shaped by a consideration of the various possibilities generated from a consideration of pathways. Also, generally, developmental pathways are described in terms of a small subset of the large number of questions and ideas that they evoke, suggesting that they have not been employed to push the boundaries of current knowledge.

In this section, we outline the scope of the concept when applied to development; we then provide two illustrations of the principles, before going on to a more detailed consideration.

At its simplest, the idea of the pathway suggests a route that is traveled over time, in which there are constraints over the directions the traveler can take, and there is an ordered sequence of events or experiences; hence, the outcome is to a significant degree predictable. The metaphor opens out, and becomes highly productive, if we envisage a traveler (walker) taking one of a number of possible pathways over a changing terrain, for example, encompassing relatively easy walking before climbing up steep mountainous paths. If developmental pathways resemble such physical paths, we can make predictions, such as that there will be phases of the journey where the path taken by an individual is highly predictable but punctuated by points at which choices are made among different paths. Paths may run in parallel, diverge, and converge; points on a path are both destinations or outcomes and starting points for further development; different paths may arrive at the same destination; the physical characteristics of a path may change considerably, as it crosses different terrains, while remaining the same path. The pathway metaphor also provokes ideas regarding mechanisms in development. For example, there are multiple ways in which decisions regarding which path to take can be made. They can be based on an overview of the ultimate aim or destination of the journey, perhaps using a map, or they may be determined by more immediate factors, such as whether the visible path looks easy or difficult. A path may be chosen because it is desirable, or because it is the only one remaining after others have been rejected, for example, because they seem too risky. Decisions at any one point are also often influenced by the cumulative effects of the journey on the traveler. The weary walker is likely to choose the easier path! Furthermore, the choice of path may be the result of the

joint effects of such different mechanisms and may vary as the path is traversed. It may be possible by observing the pathways taken by large numbers of people to identify subgroups who make predictable choices. In other words, under some conditions, use of pathways may provide an indication of a taxonomy of travelers! This is by no means an exhaustive overview of the ways the metaphor of pathways may inform questions in development and psychopathology.

ILLUSTRATIONS

By way of illustration, we present two diagrams that represent the use of pathways in developmental psychopathology. The first (Figure 7.1) is drawn from our own work that examines the impact of childhood sexual abuse on the risk of subsequent adult depression (Hill et al., 2001). The second (Figure 7.2) represents the results of a path analysis of the development of Conduct Disorder symptoms in boys (based

on Morrell & Murray, 2003). We briefly consider each in turn, returning to them later for further consideration.

Figure 7.1 shows how a sequence of experiences in childhood and adulthood is associated with adult depression. From a common starting point (level of risk), the different experiences and choices are used to define paths, the slope of each path reflecting the degree of change in risk of depression its choice results in, and its thickness reflecting how frequently that path is taken by the women of this general population sample. There is no selective display of paths, although those paths that are very rarely taken could be omitted. This diagram clearly emphasizes bifurcation, multiplicity of routes, and distinguishes the size of the effect from the relative frequency of different pathways.

Figure 7.2 is a traditional path diagram commonly associated with the reporting of results from analysis using structural equation modeling (SEM) or an equivalent set of path analysis regressions. From the outset, we are clearly

Figure 7.1 Pathways with high and low risk of depression in adulthood.

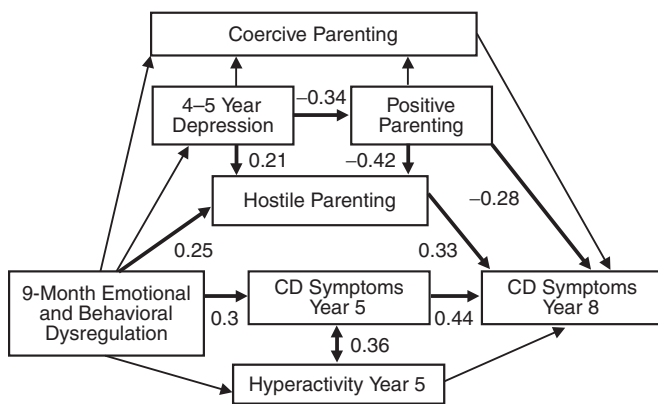

Figure 7.2 Path analysis of development of conduct disorder symptoms in boys. Adapted from “Parenting and the Development of Conduct Disorder and Hyperactive Symptoms in Childhood: A Prospective Longitudinal Study from 2 Months to 8 Years,” by J. Morrell and L. Murray, 2003, *Journal of Child Psychology and Psychiatry*, 44, pp. 489–508.

dealing with something quite different. The variables are being considered as continuous and not discrete, and how a path is interpreted in such a diagram depends to a substantial extent on the configuration of other paths, in particular on the connecting paths that have been excluded. Whether a path is included or not commonly rests on a priori theory, the empirical fit of the overall SEM and on the statistical significance of or improvement in fit on adding a particular path. In this diagram, paths significant at the $p < .05$ are shown in bold. When several paths converge on an outcome, it is not explicit, indeed it is no longer true, that a given individual reaches that outcome by means of one path only. Thus, there are three main paths to high conduct symptoms at age 8, and a child with earlier conduct symptoms and exposed to low levels of positive parenting and high levels of hostile parenting may be on all three paths at once. The magnitude of a path is usually described by a standardized path coefficient. What the diagram emphasizes is the relative importance of variables, which is a combination of the magnitude of the effect of that variable and the variability of that variable in the sample; in particular, it emphasizes sequences of important variables by which effects are transmitted forward in time.

Thus, it is clear that although both representations draw on and illustrate developmental pathways, they do so in quite different ways. Before we can assess their relative advantages, we need to explore in more detail the features and implications of supposing a developmental pathway.

FEATURES OF DEVELOPMENTAL PATHWAYS

There are numerous aspects of the metaphor that require interpretation as features of developmental pathways.

Pathways as Deterministic

“A developmental perspective implies that changes in social behavior are related to age in an orderly way” (Patterson, 1993). However, most of us believe development involves rather more than that. Rutter and Rutter (1993) add to this that “change . . . is carried forward in some way that has implications for a person’s pattern or level of functioning at some later time.” Development thus involves both change over time that follows a pattern common to all, but also interindividual differences and the mechanisms by which such individual differences persist and evolve. The notion of pathways plays an important role in emphasizing both of these aspects of development. Indeed, the restriction in the direction of travel and movement implied by a pathway strongly presupposes persistence. However, it does not necessarily imply persistence of, say, symptoms, but rather, lawful sequences that may involve symptomatic discontinuity.

There are major influences on development, such as whether a child has a Y chromosome, that act as a persistent determinant with respect to some outcomes, such as hormonal status and physical characteristics. However, generally, the concept of a pathway in development is of more use in understanding the nature of continuities that entail some, or even considerable, uncertainties. Then the concept refers to sequences in which a set of circumstances, processes, or behaviors at one time, when contrasted with an alternative set of circumstances, processes, or behaviors, is associated at some later time with an increased likelihood of one outcome rather than another.

A Pathway Implies a Developmental Sequence

That B is reached after A is intrinsic to the concept of a pathway. The strong interpretation when applied to development might be that A has to occur before B can take place, and that A cannot follow B. The pathway concept requires that time passes after A is left and before B is reached. In particular, developmentally it may be the amount of time that passes that is crucial or age-related developmental stages that are the key.

In practice, these ideas are valuable but rarely amenable to such precise application. Certainly, age-related milestones, such as the appearance of attachment behaviors in

response to threat at 6 to 9 months, are characteristic of processes in normal development, and the development of particular areas of competence *may* be necessary for others. For example, the ability to solve false belief tasks, taken to provide evidence of the development of a theory of mind, probably precedes and is clearly relevant to social competences that involve taking another's perspective. However, the concept of developmental milestones implies a functional unity that may not be present. In this case, there does not appear to be a general perspective-taking capacity that emerges fully formed. Rather, the same children show different capabilities in different contexts, and different perspective-taking competences appear at different ages (J. Dunn, 1996). The capacity to solve formal tests of theory of mind, such as false belief tests, might be expected to precede the ability to deceive in social interactions, supporting a pathway concept. However, children who fail false belief tests show deception in social interactions in some contexts (Newton, 1994).

In spite of these complexities, there are clearly developmental progressions in the range and sophistication of children's capacities to manage competing demands or rights within social interactions, and these are highly relevant to the development of psychopathology. For example, physical aggression reported by parents appears toward the end of the 1st year of life and increases until around 2 years of age and then declines (Tremblay et al., 1999). This decline is probably in part related to the development of alternative methods of solving social conflict. J. Dunn, Slomkowski, Donelan-McCall, and Herrera (1995) found that at age 33 months, children were less able when angry or distressed than at other times to sustain their reasoning powers, but by 47 months, when assessed with siblings, they were more capable of using reasoned argument when they were angry. Even if it could be shown that a failure to develop the capacity to use reason during conflict predicted persistence of aggression, or predicted its increase, it would fall short of the requirement that A has to precede B. However, it would support the role of an age-related normal developmental milestone as a protective factor against persistent aggression.

Developmental Pathways as Prediction

The metaphor of the pathway indicates that we know where it goes, what influences the traveler, and how the traveler is influenced. In other words, it implies simultaneously prediction and explanation. However, developmental investigations of psychopathology may fail to provide these, at least at the outset. This is particularly the case where a

pathway is thought of as an orderly sequence of behaviors or symptoms over time. For example, a range of taxonomies of antisocial pathways during childhood have been advanced (Loeber, 1991; Moffitt, 1993; D. F. Nagin & Tremblay, 1999), and several recent studies have sought to refine them (e.g., D. F. Nagin & Tremblay, 2001). This has been done without proposing mechanisms. Nevertheless, the ultimate aim of refining descriptive taxonomies of pathways is to provide an improved characterization of the classes of individuals against which to set the investigation of mechanism.

In straightforward taxonomies, symptoms seen at one time are predictive of the same or analogous symptoms at a later time. However, pathways may be composed of orderly change in intensity or type of symptoms, for example, with age (D. F. Nagin & Tremblay, 2001) or type of symptom. That orderly change may result in an evolution in symptoms that extend into other domains than those of the early symptoms. In criminology, among adolescents this is often viewed as an accumulation process as individuals extend their repertoire of types of crime. This leads to the idea that the variety of crimes rather than the frequency of crimes should be used to measure progress along a criminal pathway. However, if we extend the time frame, both starting earlier and following further into adulthood, then we see some symptoms that become less prominent while others are acquired that could be regarded as drawn from a rather different domain. Moffitt (1994, p. 12) describes such potential heterotypic continuity in the sequence "biting and hitting at age 4, shoplifting and truancy at 10, selling drugs and stealing cars at 16, robbery and rape at 22, and fraud and child abuse at 30." We are able to characterize some of the distinctive features of those on different pathways, and from these features hypothesize about the potential mechanisms that form the link in the pathway. In this case, Moffitt and colleagues (Moffitt, 1993; Moffitt, Caspi, Dickson, Silva, & Stanton, 1996) suggest that the underlying mechanisms include neuropsychological dysfunction, impaired linguistic skills, impulsivity, and a hostile stance toward others.

Pathways as Distinct

A direct translation of the idea of a pathway refers to an individual who is following one route, and by definition cannot be following others. This applies clearly to circumstances where a person is either in or not in some state, or to binary choices. For example, a child is either in school or out of school, and a girl is either pregnant or not pregnant. These

states are therefore candidates for markers or choice points on a pathway.

However, an individual's circumstances or characteristics are multifaceted. For example, the same child can be depressed and good at schoolwork. One pathway may be envisaged in which childhood depression is a factor that links earlier to later development, and academic performance may be a factor that links a different set of early developmental features to later ones. Here, then, a pathway is conceived of as a sequence of parallel processes, symptoms, or events, several of which may apply to any one person. In the same way, there are numerous metabolic pathways that may be in different states within the same individual. This fundamental distinction between pathways that are mutually exclusive and differentiate individuals, and ones that refer to sequences of processes or qualities, may in many respects become blurred. For example, teenage pregnancy may matter in development because of its association with loss of education, work opportunities, or social support. Each of these may have the predominant role in relation to subsequent developments, and each of these varies both among those teenagers who are pregnant and those who are not. We might therefore conclude that what matters is a particular aspect of functioning rather than an event that either does or does not happen, in which case, the concept of the pathway shifts from one that entails individuals to one that entails sequences of processes. This allows for such possibilities that a pathway may be pathological for some but not for others, a possibility clearly falling within the capacity of the physical pathway metaphor where fitter and more experienced individuals may choose a route that would be for others too strenuous. Conversely, taking the example of childhood depression and academic performance, each of these may be thought of as contributing to two pathways of succeeding processes, or to the generation of four groups representing four discrete person-based pathways.

Continuity Punctuated by Change

Developmental approaches almost always look to early childhood as the shaper of all that follows, that most of what we observe is a maturational unfolding. However, the concept of a pathway draws our attention to the possibility that different influences may operate at different times, or the same influence may operate differently at different times, and that discrete events may have long-term consequences. Changes, reflected in clear breaks with the past, often referred to as turning points, are natural elements of a pathways model.

In developmental neurobiology, pathways have a role both as a microlevel literal description and as a macrolevel metaphor at the level of the development of the whole organism. A macrolevel normal developmental pathway requires that the early growth of neuronal pathways in the brain and their subsequent trimming occur appropriately. This involves both a propitious set of genes and exposure to the right environmental stimuli at the right time. Failure to acquire experience and skills during the period when neuronal trimming relevant to that brain capacity is occurring can be permanently disabling. This was vividly demonstrated by Hubel and Wiesel's experiments into the effects on the development of the visual cortex of cats and monkeys of the timing of visual stimulus. Animals reared with one eye sutured closed had no vision in that eye and had shrinkage of the lateral geniculate body serving that eye, diminution in the number of connections to the visual cortex, and in the cortex a shift in the number of connections from the deprived to the nondeprived eye (Hubel, Wiesel, & LeVay, 1976). Crucially, this effect was seen only if the visual deprivation occurred in the first 3 months. After that, even prolonged deprivation had no discernable effect. The general principle suggested by these experiments is that neuronal connections can be modulated by environmental influences during a critical period of postnatal development. Hubel and Wiesel speculated that other aspects of brain functioning, such as language, complex perceptual tasks, learning, memory, and personality, may have different programs of development that are similarly sensitive to specific environmental inputs at some points, but not at others. Such sensitivity of the nervous system to the effects of experience may represent the fundamental mechanism by which the organism adapts to its environment during the period of growth and development.

Studies of the effects of early postnatal disruptions of the mother-infant relationship in rodents and nonhuman primates have amply supported this view. In rodents, early separation from mother leads to persistent alterations in neuroendocrine functioning (Sanchez, Ladd, & Plotsky, 2001). Furthermore, these alterations are accompanied by behavioral changes. Huot, Thrivikraman, Meaney, and Plotsky (2001) found that in rats, early postnatal separation was associated with later preference for alcohol (ethanol). This effect was mediated via altered corticosteroid responses to stress. The mechanisms are complex and are likely to involve gene expression and altered density of neurons in structures such as the hippocampus (Huot, Plotsky, Lenox, & McNamara, 2002). Two points are particularly relevant to the concept of pathways. First, postnatal maternal separation has different effects on sub-

sequent neuroendocrine function, depending on its timing. Second, although the effects of maternal separation are long-lasting and mediated via genetic mechanisms, subsequent experiences can influence some aspects of the outcome. Rats exposed to postnatal separation and subsequently provided with environmental enrichment showed reversal of the hypothalamic-pituitary-adrenal (HPA) and behavioral responses to stress, but not of the expression of corticotrophin-releasing factor (CRF) mRNA (Francis, Diorio, Plotsky, & Meaney, 2002).

Extensive work into Old World rhesus monkeys has revealed the profound effects of early disruption of the mother-infant relationship. Mothers exposed to unpredictable foraging regimes become less responsive to their offspring, who develop insecure patterns of attachment (Rosenblum & Andrews, 1994). Over time, they become less socially competent, more fearful, are hyperresponsive to stressful stimuli, and show persistent alterations of corticotrophin-releasing factor, somatostatin and biogenic amines in the cerebrospinal fluid (Coplan et al., 1998). Widespread and persistent effects on behaviors and neuroendocrine functioning following separation of rhesus monkeys from their mothers have also been demonstrated.

Bolton, Park, Higgins, Griffiths, and Pickles (2002) found that among children with tuberous sclerosis, almost all those with temporal lobe epilepsy with onset before 15 months later met diagnostic criteria for Autism, whereas this was rare among other children with tuberous sclerosis, even those with temporal lobe epilepsy, provided onset was later. These researchers speculated that the epilepsy disrupted selective brain development during the period when children would normally be acquiring metarepresentational and theory of mind skills.

Particular events may also have long-term consequences if they open or close opportunities. Occasionally, these are quite formal and explicit, such as the substantial employment restrictions placed on ex-offenders in many U.S. states (Dale, 1976). This represents an extreme element of the potentially more pervasive problem of labeling. Loeber and Leblanc (1990) argued that labeling theory is the only truly developmental criminological theory. Primary deviance may arise for a multitude of specific reasons, but once enacted, secondary deviance follows as an adaptive response to societal reaction to this primary deviance. The original causes recede into the past, to be replaced by contemporaneous societal disapprobation, degradation, and isolation. Link (Link, Cullen, Struening, Shrout, & Dohrenwend, 1989) argues that in the mental health context, the negative consequences occur through their impact on self-image, expectations of rejection, and withdrawal,

leaving the individual poorly equipped to deal with life's vicissitudes. Secondary deviance thus becomes likely. The emphasis is incremental, consistent with a stepping-stone perspective and of a pathway that constrains possibilities for positive change.

Pathway Networks and Equifinality

Almost any geographical map shows a network of paths. Our discussion up till now has largely presupposed that different paths diverge. Although that may be almost a logical necessity when considering one-step links from a single origin, this is by no means the case for the longer journey. Pathways offering the opportunity to rejoin a nondeviant pathway may be frequent. Turning points, mentioned earlier, represent clear examples. Thus, Rutter and colleagues (Pickles & Rutter, 1991; Quinton, Pickles, Maughan, & Rutter, 1993) found evidence for positive school experience and the gaining of a nondeviant supportive partner as paths that could enable some to be diverted from the pathway leading from childhood Conduct Disorder to poor adult social functioning. In fact, the main pathway appeared dominant, with rather few individuals either finding or choosing these turning-point paths. Nonetheless, for those who did, the effects appeared substantial, these paths seeming to take them back to something close to the nondeviant pathway, at least in the short run. The extent of continuity from child conduct problems is still subject to considerable debate (Zoccolillo, 1993), but typical figures would suggest that because so few were diverted along these particular paths, other unidentified diversionary paths or turning points and processes must exist.

While pathway divergence may be expected close to the origin, so, too, it is natural to expect a multiplicity of pathways converging on a destination. The concept of equifinality, that there may be different ways of reaching the same end state, has received considerable attention (Cicchetti & Rogosch, 1996). For example, it seems likely that there are many developmental determinants of Major Depression in adult life, and that some of these act additively to increase risk, and others are relevant to subgroups, suggesting distinct pathways (Kendler, Gardner, & Prescott, 2002). It is well established that the role of social adversity in precipitating episodes of Major Depression in adults depends on the number of previous episodes the individual has experienced. Life events have a decreasing role with increasing numbers of episodes (Kendler, Thornton, & Gardner, 2000). However, in the presence of high genetic risk, life events are not strongly associated even with early episodes of depression (Kendler, Thornton, & Gardner,

2001). Thus, in relation to any given episode of Major Depression, there may be one pathway in individuals at low genetic risk that entails life events combined with other sources of vulnerability, possibly related to childhood experiences (Brown & Harris, 1978; Harris, Brown, & Bifulco, 1990), and another pathway in which these factors play a part but in which mechanisms associated with previous episodes of depression are prominent. And there may be a yet quite different pathway to Major Depression in individuals at high genetic risk.

Similarly, there may be different pathways from childhood adversities to depression, depending on the nature of the adversities. Associations between poor parental care (reflected in neglect, lack of supervision, or institutional care) and adult depression and between child sexual abuse (CSA) and adult depression have been identified in numerous studies of referred and general population samples (Fergusson & Mullen, 1999; Kendler et al., 2002; Nelson et al., 2002). Recent studies of the relationship between age of onset of depression and early childhood experiences suggest different pathways. On the basis of six waves of data collection up to age 26 in a representative birth cohort in New Zealand, juvenile-onset (before age 17) was found to differ from later, adult-onset depression in several key respects (Jaffee et al., 2002). Juvenile-onset depression was associated with an increased family history of antisocial behaviors and with indices of family instability such as loss of a parent through death, separation, or divorce, but not with CSA. The juvenile-onset group had also shown more evidence of other mental health problems in childhood and adolescence, such as conduct problems and hyperactivity, and were more likely to have been assessed as having poorer motor skills and greater temperamental inhibition. By contrast, those with adult-onset depression, compared with individuals with no history of depression, had an increased rate of CSA and residence changes, but not any of the other indices of family instability. Hill, Pickles, Byatt, and Rollinson (2004) found similar differences in a general population sample of women age 25 to 35 assessing childhood risks and psychopathology retrospectively. Juvenile-onset depression was associated with multiple indices of early childhood psychopathology and with poor parental care. It was also associated with poor social functioning in childhood, teenage pregnancy, and poor social functioning in adult life. Women with adult-onset depression had functioned well as children and had experienced few adversities. The juvenile- and adult-onset groups differed markedly in their histories of CSA. Juvenile-onset depression was associated with a history of sexual abuse involving intercourse, but adult-onset depression was associated with contact CSA without intercourse. Hill et al.

hypothesized that the juvenile-onset pathway involves early interactions and transactions between symptomatic behaviors, impaired functioning, and multiple adversities, including possible post-traumatic symptoms associated with severe CSA. By contrast, well-functioning children without multiple adversities, and indeed often with supportive families, who experience CSA that does not involve intercourse use a coping strategy that enables them to maintain good functioning in childhood, but this may confer vulnerability in adult life, perhaps when involved in adult sexual relationships.

It may be that the question of whether different pathways arrive at the same point depends on the way that point is defined. Phenotypes in psychopathology are generally, rather crudely, characterized by symptoms rather than by mechanisms. In most cases, therefore, we do not know whether pathways converge to one common mechanism underpinning psychopathology, or there are different mechanisms underpinning the same symptomatic appearance. It is possible, for example, to envisage convergence to a final common cognitive mechanism for depression, one not involving life events and another that does. In the first, there is an interplay between self-devaluative cognitions and normal low mood, leading to a downward spiral and hence to depression (Teasdale, 1988), without the involvement of life events. In the second, life events interact with self-devaluative cognitions, leading to a similar downward spiral (Lewinsohn, Joiner, & Rohde, 2001). Equally, the same symptom complex may arise from different physiological or psychological mechanisms, in which case it might be argued there is not true convergence of pathways. For example, Major Depression is associated with altered reactivity of the HPA axis and reduced hippocampal volumes, but there are indications that this is the case only following a history of child maltreatment (Heim, Newport, Bonsall, Miller, & Nemeroff, 2001; Vythilingam et al., 2002). This might indicate that abnormalities of the HPA are implicated in depression that is associated with child maltreatment, but not in depression that has other origins. In that case, although different pathways appear to converge on the same condition, there is no convergence to a common mechanism.

Mechanisms May Vary Over Time along a Developmental Pathway

The pathways metaphor has the potential to free up our thinking in relation to mechanisms in development. It includes, for example, the ideas that different mechanisms may operate at different points in a pathway. We apply this thinking to a consideration of antisocial pathways.

Overall, it is likely that the life-course-persistent pathway for antisocial children represents, to a substantial degree, the unfolding, in an orderly sequence, of the consequences of a vulnerability arising from a mixture of cognitive and temperamental risks (Hill, 2002; Moffitt et al., 1996). Furthermore, many of the well-established correlations of life-course-persistent antisocial behavior problems with environmental adversities, such as harsh parenting, probably reflect shared genetic influences rather than purely environmental contributions to the pathway. However, even where there is substantial stability over time arising from individual psychopathology, a variety of processes act simultaneously and cumulatively and may influence or participate in pathways. Family, school, peer, and neighborhood environments are commonly relatively stable and therefore tend to exert relatively consistent influences over time. The child is in constant interaction with those around him or her and at each stage and in each social realm may be significantly creating the environment (evocative interactions) and selecting environments (proactive interactions; Caspi & Moffitt, 1995; Plomin & Bergman, 1991). Maladaptive behaviors can therefore be maintained by interactional styles by progressive accumulation of their own consequences and by evoking maintaining responses from others.

Equally, there are numerous points in development where the direction of the pathway may be altered. For example, the temperamental vulnerability for some forms of antisocial behaviors is thought to consist of a tendency to show intense irritability in response to everyday demands, such as diaper changes. This in turn may affect parents' behaviors so they avoid situations that result in distress or attempt to quickly dampen the distress, with the consequence that neither the parent nor the child develops effective ways of managing negative emotions (Keenan & Shaw, 2003). If this is correct, then steps in the pathway include an effect of the child's behavior to increase ineffective parental responses to intense negative emotions *and* an effect of this parenting on the child's subsequent capacity to deal with negative emotions, for example, with peers. Once antisocial behavior problems have become established, parenting style may cease to have an effect, or different aspects of parenting may become more relevant.

Nature of Pathway Risk May Change with Development

The risk mechanism associated with a pathway link need not remain constant as progress is made along a pathway link. Family breakdown may present psychological stresses

in the short run, but for women and children can present longer-term financial hardship. In other cases, some aspect of a pathway may offer short-term advantages that become a risk in the longer run. School dropout can bring short-term financial benefit through early access to employment, relative economic disadvantage impacting only later on when lack of qualifications impedes career advancement. It has also been argued that pathways that bring early stress can also bring longer-term benefits. Economic and educational investment rely on this premise, but more specifically, psychological examples may exist, so-called *steeling* in which exposure to stress results in increased subsequent resilience in the face of risks for psychopathology being an example (Rutter & Rutter, 1993). The proposed mechanism for steeling effects whereby successful navigation of challenging experiences results in increased competence and self-esteem is intuitively appealing and of wide interest, but few persuasive examples exist from observational studies.

Pathways Need Not Be Universal—Mechanisms May Vary across Different Pathways

Depending on the features used to define a pathway, the experience of and risks and possible benefits from a pathway need not be the same for all individuals. This is perhaps most obvious where the environment presented by the pathway interacts with the biological characteristics of different individuals. Sex differences are often striking, particularly in relation to antisocial behavior, and various explanations have been proposed to explain the gross differences, from measurement artifact (Zoccolillo, 1993) to different thresholds on a continuous trait model (Cloninger & Gottesman, 1987; Eme & Kavanagh, 1995). However, differences in the patterns of development have also been reported. For example, very few girls show early-onset antisocial behaviour problems, and most adolescent-onset girls have poor adult outcomes. Silverthorn and Frick (1999) argue that there is thus only one developmental trajectory for antisocial girls; it is similar to the early-onset trajectory for boys in terms of the severity of risk factors but delayed due to the higher threshold for girls associated with strong socialization during elementary school, hormonal differences, different social pressures/cognitive impacts associated with puberty, and greater peer pressure. Moffitt, Caspi, Rutter, and Silva (2001, chaps. 12, 13) examined a range of childhood risk factors and personality traits for evidence of the higher thresholds suggested for Conduct Disorder in girls. They concluded that in the Dunedin sample, girls who met criteria for Conduct Disorder “do not pass a higher threshold

that requires a stronger aetiological press" (p. 158) and that previous evidence to the contrary was either based on possibly selective officially identified cases of Conduct Disorder or empirically weak studies. Evidence for sex-differentiated patterns of outcome did find support: boys with more work, substance use, and legal problems, and girls with more relationship, depression, suicide, and health problems. Developmental differences in childhood have, however, been identified by Rowe et al. (2002), who find early oppositional behavior indexing a pathway with quite different outcomes for boys and girls; for boys, it links to Conduct Disorder, whereas for girls, the pathway links to depression.

The effects of biological differences within sexes are now increasingly evident. Rowe, Maughan, Worthman, Costello, and Angold (2004) find evidence for the effects of deviant peers, a frequently cited route into antisocial behavior, being much increased for boys with high testosterone. Interactions with biological differences indexed by genotype have now also been reported, such that childhood adversity results in increased antisocial behavior for specific MAOA genotypes (Caspi et al., 2002).

More familiar interaction effects among behavioral measures can also be found. Coie, Terry, Zakriski, and Lochman (1995) followed a Black inner-city U.S. sample from third grade (age 8) with assessments at 6th, 8th, and 10th grades. Among adolescent boys, self-reported externalizing problems were not predicted by either aggression or rejection, assessed using peer nomination in grade 3. However, the combination of aggression and rejection was associated (as evidenced in a significant interaction term) with increasing levels of externalizing behaviors across the three follow-up assessment points. In girls, the results were more complex, in that only aggression predicted self-reported externalizing problems, and only rejection was associated with parental reports of such problems in adolescence. The findings for males were consistent with the hypothesis that children who both are antisocial and have peer difficulties have a more pervasive disorder that may make them more vulnerable to development of the broad antisocial personality profile in adult life (Coie et al., 1995; Quay, 1993).

Identifying subgroups or subpathways may be crucial to identifying mechanisms. This was illustrated in successive reports from the Montreal Longitudinal Study of 909 male children (Tremblay, Masse, Vitaro, & Dobkin, 1995; Vitaro, Tremblay, Kerr, Pagani, & Bukowski, 1997), attempting to determine whether deviant peers contribute to a pathway leading from earlier to later childhood antisocial behaviors. In one view, having deviant peers is part of the wider set of social difficulties of antisocial children. In

that case, any links between having deviant peers at one time and being antisocial at a later time, which might have indicated that deviant peers add to the risk by reinforcing deviance, are in fact explained by the extent of the child's earlier antisocial behaviors. This was supported by analyses of the whole sample using SEM (Tremblay et al., 1995) and is consistent with other findings from general population longitudinal studies (Woodward & Fergusson, 1999). In the alternative view, there is a contribution from deviant peers to the risk for antisocial behaviors, and the Montreal data provided evidence in favor of this possibility in one subgroup but not in others. Vitaro et al. created four categories of boys based on assessments at ages 11 and 12 (highly conforming, moderately conforming, moderately disruptive, and highly disruptive) and four groups of friends' behaviors (nonaggressive, average, aggressive, no friends). After controlling for levels of antisocial behaviors at age 11, having aggressive friends at age 11 was associated with increased delinquency at age 13, but *only* in the moderately disruptive group. Thus, both highly disruptive and conforming boys appeared to be on pathways that had already become consolidated and not susceptible to the effects of peers' behaviors, but the direction of the moderately disruptive group was still open to peer influences.

Elements on a Pathway Vary in Their Explanatory Potential

Pathways described solely in terms of symptomatic or behavioral continuities do not examine hypotheses regarding mechanisms. However, pathways can be readily constructed in which elements have explanatory potential. Studies conducted into physical abuse, social information processing in children, and aggression provide good examples. Dodge (1993) hypothesized that children who are prone to aggression focus on threatening aspects of others' actions, interpret hostile intent in the neutral actions of others, and are more likely to select and to favor aggressive solutions to social challenges (Crick & Dodge, 1994; Pettit, Poloha, & Mize, 2001), and that these information-processing biases are the result of repeated exposure to physical maltreatment. Dodge, Pettit, Bates, and Valente (1995) tested this model in a sample of 507 children recruited from kindergarten. Physical abuse documented in kindergarten was strongly associated with conduct problems in grades 3 and 4. Encoding errors, hostile attributions, accessing and favoring aggressive responses were each associated with conduct problems in grades 3 or 4 and with having experienced physical abuse. Using structural equation models, encoding errors and accessing aggressive

responses mediated the link between physical abuse and conduct problems, but hostile attributions and positive evaluation of aggressive responses did not. There was also a direct association of physical abuse with conduct problems not mediated via the information-processing variables. Thus, there was partial evidence for a pathway involving information-processing biases, but also for one or more other pathways operating via other mechanisms.

The Effects of Symptoms and Behaviors on Pathways and Dynamic Relationships with Mechanisms

It is common for symptoms, whether thought of dimensionally or categorically, to be considered only as outcomes of preceding processes. However, the pathways concept envisages them also as possible influences on subsequent functioning. This is well illustrated in the case of depression in adolescence. Continuities between adolescent depression and episodes in adult life are well established (Harrington, Fudge, Rutter, Pickles, & Hill, 1990) and may represent a disorder that starts in adolescence and recurs through adult life. However, it is probable that episodes of depression themselves alter the risk of later episodes through social or cognitive mechanisms. Increased negative life events and excessive emotional reliance on others, both associated with risk for further depression, were found in adolescents in a general population sample after they had recovered from an episode of Major Depression (Rhode, Lewinsohn, & Seeley, 1994). Episodes of depression may also alter the likelihood of further episodes through an increase in cognitive vulnerability. According to Teasdale (1988), episodes of depression increase the strength of association between mood and dysfunctional cognitive processing. Cognitive risk for recurrence arises from the ease with which these patterns of processing become reestablished, following recovery, in the face of mild negative affect. In support of this hypothesis, Lewinsohn, Allen, Seeley, and Gotlib (1999) found an increased association between low mood and dysfunctional thinking styles following adolescent depression, and this in turn predicted recurrence.

The pathway analogy suggests that the path choices available at any location are the same regardless of the path taken by an individual to reach that location. This feature is often referred to technically as a Markov, first-order autoregressive, or memory-less property, the last referring to how future progress depends on the current state (location) but not on the past. This is a very strong assumption, but one that is testable. Moreover, elaborations of the pathway analogy that take into account how travelers bring with them the experience of previous routes and use this infor-

mation in choosing their next path allow this assumption to be relaxed.

Pathways through Contexts

A wealth of theory and empirical findings is available explaining associations at individual and aggregate levels, but work integrating these is much scarcer. Leventhal and Brooks-Gunn (2000) provide a review of neighborhood effects and extend the ideas of Sampson, Raudenbush, and Earls (1997) to an integrated developmental model. With respect to antisocial behavior, several studies (e.g., Loeber & Wikstrom, 1993; Sampson & Groves, 1989; Sampson, Raudenbush, & Earls, 1997) point to the apparent importance of parental monitoring and discipline, peers and neighborhood population instability, and social efficacy. However, in general, the research findings are too scant to draw any firm conclusions about potential pathways. Thus, for example, Kerr and Stattin (2000) argue that most published measures and effects of parental monitoring reflect adolescents' own willingness to disclose to parents and that parents themselves have little independent effect.

SOME LIMITATIONS OF THE PATHWAYS CONCEPT

It is evident from the preceding discussion that the concept of pathways can provide a valuable means of structuring questions and hypotheses regarding development and psychopathology. However, there are issues to be addressed in development that are not opened up by the pathways metaphor. One concerns causality in development. The pathways analogy provides an excellent framework for what might be termed the Humean account of causality in terms of whether B follows A, and whether A is necessary or sufficient for B (Hume, 1777/1902). Given the multiple potential causal factors and outcomes in development, sorting this out is a major and essential task. However, when we try to take more from the metaphor, we could be misled into a rather simplistic model of development as essentially channeled and open to switches of direction at key points. Generally, the causal models that we have considered so far do not suffer from such limitations, largely because causal accounts that are not necessary consequences of the pathways framework have been imported. Thus, for example, various social cognitive hypotheses have been introduced into the causal explanation of the origins or maintenance of antisocial behaviors in children, and these can be expressed within the pathways paradigm but are not necessarily illuminated by it. The models that inform these hypotheses are

ones concerning attributional processes, perspective taking, and affect recognition in social contexts.

The general point is that the developing individual, in childhood and adult life, is an active participant, in interaction with the environment, and that, except at pathway junctions, this is not the image conjured up by the idea of a pathway. Furthermore, individuals reach particular points on developmental pathways with competences or vulnerabilities that have been shaped by constitutional factors and by experience. For example, the contrast between an effect of deviant peers on moderately, but not highly aggressive, boys (Vitaro et al., 1997) can be expressed in terms of two different pathways. However, the key question is, What do boys in the moderately aggressive group bring to their interactions with peers that the highly aggressive do not, and what influences their responses? Differences in information processing, executive function, autonomic responses, and quality of relating with the peers are all candidates (Hill, 2002).

There is a risk, also, that the pathways metaphor may place too much emphasis on discrete events or stages. Clearly, the Humean analysis requires that event A and outcome B can be identified, and that is, in general, how developmental studies are conducted. However, often these analyses are, at best, illuminating snapshots of an evolving process and, at worst, simply artifacts of the timing of measurements. This is well illustrated by J. Dunn's (1996) discussion of the relationship between children's social experiences and their subsequent abilities to solve theory of mind tasks. Experiences of pretend play and participation in disputes and conversations about the social world have all been found to be associated with subsequent ability to solve theory of mind tasks. However, as Dunn points out, children's capacities for perspective taking are likely to influence their participation in these social interactions and in turn, their participation to enhance perspective taking. It may not be possible to carry out studies that capture events over the time frame of such mutual influences. Within a pathways model, one might distinguish, for example, between a path where such mutual interactions take place, and one where they do not, but the causal processes within the pathway, and especially their temporal relations, require other models.

The issue of the time course of causal influences in development is also not readily envisaged in a pathways framework. The questions center on the time over which an influence has to operate before it makes a difference, and on the durability of such influences. For some influences, such as early exposure to adverse parenting in non-human primates, timing rather than duration appears to be

crucial and, we have argued, is well encompassed by the concept of a pathway. Similarly, discrete traumatic events may have long-term consequences (Bolton et al., 2002; Hill et al., 2000), and these also are usefully interpreted within the pathways analysis. However, the pathways model does not obviously suggest that, depending on the nature of the causal factor, different periods of exposure may be necessary before one or the other pathway is joined. For example, close relationships in childhood and in adult life are associated with better functioning in the presence of risks, such as other adverse relationships or institutional care (Rutter, Quinton, & Hill, 1990), and therefore can be thought of as leading to a switch from a higher- to a lower-risk pathway. However, we have no idea how long a good relationship has to last before it becomes protective, and indeed how many answers there are to that question. It may be that for some purposes, such as solving practical problems, a good relationship takes immediate effect, and that for others, such as engendering attachment security or reducing proneness to depressogenic cognitions, it may take longer.

Similar considerations apply to the durability of protective factors. Some effects we may expect to endure only as long as the relationship, and others to last several years after a relationship has ended. Studies that are able to titrate duration of exposure to impact on development are rare. However, naturally occurring variations in the time infants and young children spent in Romanian orphanages before adoption have provided an opportunity to examine the issue (Kreppner et al., 2001; Rutter, Pickles, Eaves, & Murray, 2001). Rates of atypical attachment behaviors, inattention, and overactivity and of quasi-autistic features were found in the adoptees, and the levels were associated with how long they had been in an institution before adoption. Many of these abnormalities attenuated over time, suggesting that the impact of institutional rearing, to a certain extent, falls away.

The pathways metaphor is also limited in its implied conceptualization of the landscape. Development entails much more than a progression over time, even one that is described as occurring in interaction with the environment. The child functions in a social and educational milieu that is also developing, in that peer competences are increasing, as are adult expectations. This means that ways of functioning that served well at one point in development may not be effective subsequently. For example, the difficulty for a child who has not progressed with his peers in developing the capacity to hold on to a line of reasoning in an argument (J. Dunn et al., 1995) is not only that he has not acquired the skill, but he has to find a way

of being socially effective with peers who have. They are likely to be more effective negotiators and also to earn the approval of adults whose age-related expectations have changed. The experiences of social ineffectiveness and criticism from adults are, in turn, likely to increase the likelihood that he will use aggressive “solutions” in social interactions.

Finally, unlike the case of the great majority of travelers, who set out with the intention of reaching some chosen destination and among whom some may even plan their route with a map, we attribute very little foresight to those on developmental pathways. Causal processes in science are assumed to work from the past and current to the future, and explanations involving intentions and expectations test the limits of this restriction.

CAUSAL AND FORMAL MODELS

The frequent use of SEM as the analysis environment in which to operationalize developmental pathways both illustrates the strong connections between notions of causal pathway and of developmental pathway but has restricted the more general exploration of their interrelationship.

Causal Pathways

The literature on developmental pathways often takes for granted the causal status of suggested pathways. There are at least two ways in which the causal analysis literature is helpful: methods of analysis and formal representation. Different methods of analysis, and the evidence that each method offers as to the nature of a causal link, are discussed in the next section. We consider here the formal representation of causes, many of which involve quite explicit use of paths.

In their overview of causal modeling methods, Greenland and Brumback (2002) identify graphical models (e.g., Robins, 2001), potential-outcome (counterfactual) models (e.g., Rothman & Greenland, 1998), sufficient-component cause models (Rothman, 1976), and structural equation models (Pearl, 2000) as the distinct and largely complementary alternatives. We cannot provide a complete overview of each; instead, and in a most uneven fashion, we point to particular aspects that seem to have special relevance to developmental pathways. Consideration of potential-outcome (counterfactual) models we defer to the next section.

Graphical Models

Graphical models look very much like SEM path diagrams, but without the boxes, circles, and arrows for errors. They are also nonparametric and thus in themselves not estimation tools. Their primary use is in identifying the conditions under which independence and conditional independence apply (Greenland, Pearl, & Robins, 1999). They are thus very useful in showing what analysis or experimental design does or does not lead to the estimation of effects of one path uncontaminated by the effects of another. As an example, consider Figure 7.3.

If we were interested in the direct path from X to Y, we might think that examining the relationship between X and Y in a sample selected to be homogeneous for Z would allow us to do this, as we would have eliminated variation in Z and thus controlled for the indirect path from X to Y via Z. Graphical modeling theory tells us that such an approach is flawed, because selection on the basis of Z induces correlation between X and U where none existed before, with the result that the simple relationship of X and Y in the sample selected for a specific value of Z is confounded by uncontrolled variation in U (Robins & Greenland, 1992). We should therefore be wary of examining relationships from childhood to adulthood in a group selected for some adolescent outcome.

Structural Equation Modeling Path Diagrams

From its name alone, path analysis would seem to be a highly relevant tool for examining developmental pathways. Path analysis, first systematically developed by Sewall Wright (1921), exploits linearity assumptions to allow the covariance between two variables on a path diagram to be decomposed into contributions arising from each legitimate path that connects them, with simple rules for determining the legitimate paths (Heise, 1975; Wright, 1934). Implicit in these diagrams is the fact that

Figure 7.3 Confounding of the causal relationship of X to Y by Z.

we are modeling these sets of variables as a set of simultaneous equations. These would now be commonly estimated in software for SEM.

If, to the traditional diagram, a residual variance is added to each variable in the form of a double-headed arrow running both from and to that variable, then the path-tracing rules for legitimate paths can be reduced to (1) trace backward from a variable, (2) change direction at a two-headed arrow, then (3) trace forward. These rules allow us to identify how the value of a later variable can be influenced by an earlier variable either by a direct path or by an indirect path via another variable. Multiplication of the (standardized) coefficients along each chain gives the expected (standardized) covariance for that path, and these may be summed to give the total, direct and indirect expected covariances (or effects).

But do they correspond to paths that embody the features we have described for a developmental pathway? What have these analyses and diagrams got to do with pathways of the kind that we have been considering? Clearly, when applied to cross-sectional data, the idea that these paths could describe developmental pathways is not justified. Nonetheless, what about applications to longitudinal data? It is clear that many authors using these methods with developmental data treat these paths as synonymous with developmental pathways. In fact, their equivalence is very far from clear. In SEM-related path diagrams, whereas we commonly speak as though different paths relate to different individuals, in fact they relate to the characteristics of individuals. Individuals with high scores on multiple risk dimensions have their outcome scores multiply elevated—it is as if they pass down several paths at the same time. Moreover, the complete path diagram is being presented as a description of the population process, and there is little elucidation of individual differences in that process. All individuals share common path coefficients and seem to differ only in the residual errors and disturbances.

If we consider the simplest of cases of a single pathway from X to Y as represented in the simple regression $Y = a + bX + e$, the model allows for two alternative pathways to a high value of Y . If we assume that b is positive, then the first is that from X , for which a high value of X is required. The second is through the disturbance term e , which summarizes all the other pathways not being explicitly considered. Clearly, for a given value of Y , the bigger the residual e , the more likely is the individual to have followed one of these other pathways. Thus, models either in which these variances and disturbances were given more substance or that allowed for interindividual differences in path coefficients might be preferred. Random coefficient models offer one

possibility; later, we examine one particular example of these, namely, growth curve models.

Path models can provide considerable insight into the mechanism by which variation in one variable gives rise to variation in some later variable, especially where variables that play a theoretically critical intermediate role are included. One aspect of SEM path representation that has become very widely used is the distinction and decomposition into direct and indirect effects; of particular interest is where it can be shown that there are no effects of the first variable on the last variable once the effects of the intervening variables have been accounted for. If the effects are mediated by the intervening variables and there are no residual direct effects, this is interpreted as strong evidence for their being a causal pathway. Thus, a mediating variable, usually synonymous with an intervening, intermediate, or contingent variable, “is a variable that occurs on a causal pathway from an independent to a dependent variable. It causes variation in the dependent variable and itself is caused to vary by the independent variable” (Last, 1995, p. 87). Tests for such mediation have been formulated within the SEM framework and are described later. In psychiatry, biometrical genetics, and social medicine, the estimation of direct and indirect effects has been largely synonymous with the use of path analysis and path diagrams.

There has been substantial argument for the shortcomings of path and SEM analysis from those associated with the interactionist perspective, who find such variable-based analyses unsatisfactory, preferring instead individual-based analysis of the kinds to be discussed later (von Eye & Bergman, 2003). This is related to one of the major limitations of SEM path models, namely, their inability to represent interactions. In fact, this is not a strict limitation, multiple group methods and a number of more recent methods enabling these to be considered (Schumacker & Marcoulides, 1998). Nonetheless, few substantive applications have pursued them.

Multifactorial Causation and the Sufficient-Component Cause Model

A variety of conditions have to be met before, during, or after a causal event for the effects of a cause to occur. Sometimes these conditions are not of interest; we simply assume that they are met. Such assumptions often more or less explicitly restrict the scope of the circumstances under which the cause may have an effect. However, other conditions, or the same conditions when viewed from a different

Figure 7.4 Component cause models (a) top, (b) middle, (c) bottom. Adapted from “Causes,” by K. J. Rothman, 1976, *American Journal of Epidemiology*, 104, pp. 587–592.

theoretical perspective or different point of interest, cannot be treated in this way. Instead, the presence of a condition is seen as an integral part of a more complicated causal process where the condition becomes better considered as another cause. With multiple causes, a more developed terminology is necessary.

Rothman (1976; Rothman & Greenland, 1998) has suggested that we need to consider component causes. The idea of component causes is helpful for a variety of reasons. First, they can be classified as being necessary or sufficient. If the occurrence of just one of the component causes is enough for the effects to be observed, this cause is sufficient. If all other causes may be present and yet no effect is observed unless one particular cause is also present, then this particular cause is a necessary cause.

This simple decomposition has all sorts of implications as to what we might expect to observe in our data. Figure 7.4a shows three causes—A, B, and C—influencing a single outcome Y. These causes are each sufficient: Only one needs to be present before the outcome can occur. Typically, one of these paths, say A, is a composite path representing all the other ways the outcome could occur in the absence of paths B and C. This allows us to focus on elucidating the causal mechanism relating to B and C without its being necessary (we hope) to explain every other possible way the outcome could have come about. The apparent need to explain everything about an outcome is not an uncommon stumbling block for novice researchers, and a residual composite pathway helps avoid this. It also means that we focus on the effects of B and/or

C in elevating the rate of the outcome over and above some background or base rate that would be occurring as a result of the ever-present generic path A.

To make the discussion less abstract, we consider a hypothetical case in which B is exposure to familial discord, C is deviant peer group, and the outcome Y is delinquency. Formalizing the consideration of outcome rates, the causal model suggests that in the absence of B and C, outcomes can occur only through path A, and that over some period of observation, the outcome might be observed in a proportion p_A of children. For children also exposed to and thus at risk of B, outcome occurrences will be observed for a proportion p_A through path A, and a proportion p_B through path B. Similarly for children exposed to C. Both B and C are sufficient; that is, exposure to either parental discord or a deviant peer group raises the rate of subsequent delinquency. For children exposed to both B and C, some will succumb through path A, some through path B, and some through path C. If these rates are individually comparatively small and having a deviant peer group is not associated with familial discord, then comparatively few children are exposed to both risk factors and few individuals progress down both the B and C causal paths jointly. This means that the rate of the delinquency outcome expected for children exposed to both B and C will be the simple additive sum of the proportions arising through each possible path, that is, $p_A + p_B + p_C$.

In more complicated examples it becomes necessary to separate pathways from the risk factors. Figure 7.4b shows a rather different circumstance in which both B and C are necessary to pathway 2 in order that the outcome rate is elevated over that of the base or background rate through pathway 1. Because the rate is not increased if either B or C is absent, then B and C are not sufficient causes. When they occur together they form a sufficient cause, and a sufficient cause corresponds to a pathway. This describes a circumstance of total synergy between B and C, each risk factor potentiating the effect of the other.

Figure 7.4c shows the case where B is necessary and sufficient to pathway 2, but is necessary but not sufficient to pathway 3. C is also necessary but not sufficient to pathway 3. Here the presence of C only partially potentiates the risk posed by B. Partial synergy of this kind implies that B is a component of more than one sufficient cause (pathway).

Figure 7.4a, in which the outcome rate is given by the simple sum of $p_A + p_B + p_C$, the cause-specific rates, provides a benchmark against which we can test for synergy. Table 7.1 shows the expected outcome rates in the presence and absence of B and C, the two risk factors of interest, for the complete and partial synergy models of Figures 7.4b and 7.4c.

TABLE 7.1 Expected Outcome Rates Corresponding to the Additive Models of Figure 7.4

	Figure		
	7.4a	7.4b	7.4c
P_A	A	A	A
P_{AB}	A + B	A	A + B
P_{AC}	A + C	A	A
P_{ABC}	A + B + C	A + BC	A + B + BC

An empirical test of whether there is synergy between B and C will therefore be to compare the relative fit (of expected to observed rates or frequencies) of Figures 7.4b and 7.4c with that of Figure 7.4a.

This simple classification and thought experiment delivers some straightforward expectations and criteria for describing aspects of processes. It is therefore rather surprising to realize that it is almost entirely inconsistent with the way that we have been trained and most of us actually analyze our research studies! The argument suggests that our null expectation should be that the combined effect on an outcome rate of specific component causes will be additive in their individual effects on the outcome rate. However, for perfectly sound statistical (and some good epidemiological) reasons, we have been taught that we should not combine effects additively on the rate scale but should do this on the logistic (log-odds) scale, or the log scale to which the logistic scale closely approximates when the base outcome rate is low. Table 7.2 shows the expected rates under a model that is additive on the log scale, that is, equivalent to those from a logistic regression with additive effects for two specific risk factors B and C for a study where the outcome rate is low.

What we see is that the rate expected when B alone is present is $\exp(b) \times$ the base rate. More critical, the effect when both B and C are present is not additive in their individual effects. Instead, it is multiplicative. Under the Rothman additive model, if the base rate was 1%, and each component cause resulted in further rates of 1%, then the rate expected when either B or C was present would be 2%, and when both risk factors B and C were present it would be 3%. Under the main effects logistic model, the corresponding rates would be 1%, 2%, 2%, and when both risk factors are present it would be 4%.

There are several implications. First, in the case of relatively rare outcomes and risk factors, substantial positive synergy is implied by logistic models with just main effects. Synergy is not at all synonymous with the need for a significant interaction term. Second, although our psychological theory may tend to emphasize the possibility of positive potentiation of one risk factor by another, in practice we may be more likely to find we need negative interactions in logistic regression analyses as a means of bringing the model more closely into line with the null expectations of the often plausible additive component cause model. Third, it should be emphasized that the foregoing is not a criticism of logistic regression, a form of analysis that remains a most elegant tool. But it does explain previous academic argument as to whether there were, or were not, synergistic effects, for example, the fierce debate between Brown (Brown, Harris, & Copeland, 1977), who proposed vulnerability factors for depression using an additive model, and Tennant and Bebbington (1978), who argued against their existence based on the absence of interaction in the logistic framework. The consensus among epidemiologists (e.g., Blot & Day, 1979) is that synergy does not require or equate to an interaction in a logistic regression. Moreover, this does undermine the perhaps simpleminded, but ever so appealing, interpretation that the inclusion of a risk factor as a main effect in a logistic regression represents the inclusion of an alternative pathway. It might be an approximation to it, but in fact, it more closely represents a rather different elaboration of the pathway model, to which we now turn.

Stages, Steps, and Intervening States

As yet, we have not attempted to examine the means by which Rothman's sufficient causes might take their effect. As a consequence of some unspecified mechanism, the risk factors open a channel through which maldevelopment can occur. There is no differentiation of the process along that channel, and the outcome was observed as being the result of what looked like a single-stage process. However, a substantial body of psychological theory has regarded development as progression through a series of stages (e.g., Deanna, 1976, regarding Kohlberg's stages of moral development) that provide an opportunity for identifying developmental changes in etiology: One set of risk and protective factors may influence progress to an intermediate outcome, and another set may be

TABLE 7.2 Expected Outcome Rates for Figure 7.4a with Multiplicative Effects

P_A	$\exp(A)$		= Base rate
P_{AB}	$\exp(A + B)$	= $\exp(A) \times \exp(B)$	= Base rate $\times \exp(B)$
P_{AC}	$\exp(A + C)$	= $\exp(A) \times \exp(C)$	= Base rate $\times \exp(C)$
P_{ABC}	$\exp(A + B + C)$	= $\exp(A) \times \exp(B) \times \exp(C)$	= Base rate $\times \exp(B) \times \exp(C)$

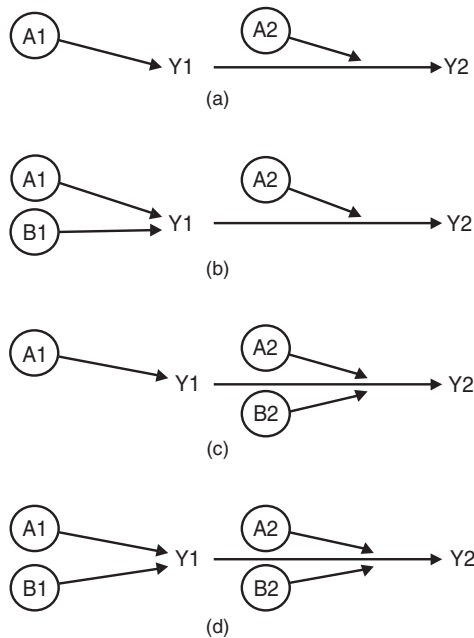

Figure 7.5 Multistep component cause model.

important in the progression from intermediate to final outcome. The supposition of a stage in fact provides a model with a remarkable range of capacities that were first elaborated for cancer development but that Pickles (1993) described more fully in the context of psychopathology.

As we did with the single-stage models, we now consider some risk factor scenarios for a two-stage process with intermediate outcome Y1 and final outcome of interest Y2.

In Figure 7.5a, background factors alone act to generate both intermediate and final outcomes. In Figures 7.5b through 7.5d, within each stage the presence of the additional risk factors, each representing a sufficient and necessary component cause with respect to their immediate outcome, acts as before in an additive fashion. However, at the second stage (and any postulated later stages), the background and risk factors cannot act on everybody; they can act only on those that have experienced the intermediate outcome Y1. Achieving the intermediate outcome is a prerequisite either to being exposed to the second-stage risk factors or to their having any effect. The result is that, unlike when combining effects within a stage, combining effects across stages is multiplicative: The larger the stage-one effect, the larger will be the number at risk to the second-stage risk factors. With background factors alone, the rate in Figure 7.5a is $p_{A1} \times p_{A2} = A1 \times A2$, whereas in Figure 7.5b it is $(A1 + b) \times A2$, in Figure 7.5c it is $A1 \times (A2 + c)$, and in Figure 7.5d with both risk factors present it is $(A1 + b) \times (A2 + c)$. With background rates of 1% and additive within-stage component-cause effects of

1%, the expected rates corresponding to Figures 7.5a through 7.5d are 0.1%, 0.2%, 0.2%, and 0.4%.

Thus, how the effects of risk and protective factors combine to increase or decrease the rate of the final outcome will depend on the transitions they impact, additive effects being expected if the factors operate on the same stage transition or multiplicative effects if they act on different stages in the sequence. A main effects logistic model is therefore rather more consistent with the idea of risk factors acting on different steps on a single but extended pathway, than it is with multiple distinct paths.

Of course, we typically do not know whether there are intermediate outcomes. Just as in cancer research we might postulate intermediate stages in cell development prior to the final stage of uncontrolled replication of malignant cells, so in psychopathology we might postulate a variety of intermediate cognitive, behavioral, or social states or circumstances en route to our final focal outcome. As we have seen, a logistic model with main effects implies a level of positive synergy between risk factors. Synergy has often been conceptualized as some form of “chemistry of the moment”—the immediate coincidence of risk factors being necessary for it to occur. By contrast, postulating an intermediate stage, together with risk factors that act on different stage transitions, provides all that is necessary for such apparent synergy. Moreover, this synergy is one in which the exposure to each of the apparently synergistic risk factors could be separated by years. We would argue that this is much the more likely way synergy occurs in psychosocial development than through chemistry of the moment. A final elaboration of the argument is that the finding of partial synergy might suggest that one risk factor may operate on both stage transitions, whereas the other operates on only one.

Staged pathways also have implications for timing. Where the intermediate stages are not observed, the effects on the final outcome of risk factors for early stages may not be observed for some considerable time, and the outcome rate may seem to lag variation in risk factor exposure: The risk factor can be removed, and yet new cases continue to appear for years. Risk factors for later stages are likely to show their effects more immediately.

ISSUES IN THE INVESTIGATION OF DEVELOPMENTAL PATHWAYS

Here we consider factors in the design and measurement of studies that allow them to be informative about the nature and existence of developmental pathways.

Longitudinal Studies Are Not Necessarily Developmental

Longitudinal research and developmental research are far from synonymous. The former refers to the method of collecting and analyzing data on individuals or populations measured over time. However, as several authors have commented (Sampson & Laub, 1997), it is a sad irony that much of the research using this method in fact is no more than a glorified cross-sectional study, and often without the researchers being aware of it. Thus, for example, many researchers use forms of random effects models that mechanically pool between-subject (cross-sectional) and within-subject (change) information, effectively confounding the precious information on change (which was the whole justification for the study) with the cross-sectional information (which we all know is suspect). Also, as Sampson and Laub point out, much longitudinal research labors under an inheritance of static theory, be that sociological or, more commonly in our case, adult psychiatric typologies.

Prospective and Retrospective Methods in Pathways Research

Prospective study is rightly seen as the benchmark, with strengths that are contrasted with the disadvantages of retrospective investigations. It is commonly asserted that retrospective reporting, typically referring back to childhood from adult life, is unreliable and is not able to provide accurate information on the temporal sequences that are essential for delineating pathways. Adults without psychopathology are prone to underreport childhood difficulties (Maughan & Rutter, 1997), not necessarily as a result of state-dependent memory, but as a consequence of the lack of mental or verbal rehearsal of events that those with poorer outcomes may have undertaken (Hardt & Rutter, 2004). Spuriously strong associations may result from shared method variance—the general tendency for reports from the same source to be correlated.

However, the time scale for the prospective investigation of pathways to adult disorders will necessarily be long, meaning that a program of research will take several generations. Furthermore, a major advantage of retrospective study is that the final steps in a pathway can be explored quite precisely, whereas the earlier ones are necessarily examined in broader outline. In the pathways metaphor, if the outcome is analogous to reaching a summit, the climber has an immediate appreciation of the final steps and a panoramic view of the pathway, one that is hazy on the details.

The validity of retrospective reports is supported where they yield findings similar to those from prospective study. We described earlier multiple differences in the early childhood antecedents of juvenile- and adult-onset depression found both in the prospective Dunedin Multidisciplinary Health and Development Study (Jaffee et al., 2002) and in the retrospective Wirral Woman's Health Survey (Hill et al., 2004). They were consistent in suggesting that there may be different pathways to adult depression, depending on age of onset, implicating different childhood vulnerabilities and adversities. The prospective study is likely to have yielded the more reliable and accurately timed assessments of childhood experiences and psychopathology, but the similarity of the findings between the retrospective and prospective studies suggests that the panoramic view afforded retrospectively was reasonably accurate.

Discrete Combinatorial Pathways, Log-Linear Models, Clusters, Types and Antitypes

Although much of the evidence for pathways has not been based on any attempt to formalize how the concept of a pathway could be operationalized, there is much to be gained by doing this. When speaking of analysis, we immediately confront a substantial fissure in statistical thinking and research experience and understanding: that between dimensional and categorical approaches. Though we should be striving to bridge this fissure (Pickles & Angold, 2003), it nonetheless is easier to organize our discussion separately.

Our first pathways diagram of Figure 7.1 shows the estimated population distribution over a sequence of dimensions. The first considers the overall average rate of depression, then that rate split by quality of parental care in childhood, then that rate split by the joint distribution of parental care and childhood sexual abuse, and eventually by the full joint distribution that includes quality of adult love relationships. That full joint frequency distribution could be analyzed in a variety of ways: as a series of logistic regressions (Hill et al., 2001), as a log-linear model, or as a cluster analysis. Within each of these there are various extensions that are perhaps particularly appropriate to the analysis of developmental pathways.

The sequence of logistic regressions, focusing on each bifurcation in sequence, clearly appeals to a perspective of chains of effects, consistent with the search for potential turning points. Although not necessary, in practice there is a tendency to assume that previous experience largely has its effects through main effects, even through the main effects of the immediately prior variable only.

This lack of memory effect implies that future development depends only on the current state, not on how it was arrived at. This Markovian property might be entirely consistent with many pathway models but may not be entirely appropriate to development. The calculation of the extent to which early stage effects are transmitted to the eventual outcome is described in Winship and Mare (1983). The method represents an elaboration of path modeling in the case of binary variables where the simultaneous equations take the probit form, and where effects of each variable may arise from two sources: the effect of the observed binary value and the effect of the latent continuous (conditionally normal) variable that may underlie the observed binary variable. This second effect arises where the binary variable reflects an underlying propensity that has been measured subject to error in categorical form. Both effects may be of interest; for example, psychiatrists might want to distinguish the effects of an actual episode of depression from the effects of a predisposition for depression, the latter reflecting genetics, among other things. Pickles and Rutter (1991) work through the path model calculus in tracing the effects of a turning-point event. Their illustration makes clear that although the concept of a chain of effects has theoretical appeal, if the effects are transmitted by the binary event occurrence only, then unless the links in the chain follow near deterministically, effects are not transmitted far along the chain before their effects fade out.

The variables that form the sequence can be characteristics of the individuals or can be features of their context or environment. That combination of individual and contextual features, with no analytical priority being given to one or the other, is a critical feature of what has become known as the “person-oriented approach.” Proponents of this approach argue for distinctive methods of analysis (Bergman, Magnusson, & El-Khoury, 2003; Magnusson & Bergman, 1990). One of these, though it predates the approach, is a form of log-linear/multidimensional contingency table modeling known as configural frequency analysis. Von Eye (1990; von Eye, Spiel, & Wood, 1996) provide a modern presentation of the approach. The basic approach consists of fitting a main effects-only model, which assumes independence among the marginal variables of the table, and then comparing the expected frequencies with those observed. Attention is focused on so-called types, combinations of variable values or cells with a much greater frequency than expected. With longitudinal developmental data, such types may represent the common developmental pathways. Antitypes, reflecting pathways less frequently taken than expected, may also be found but are typically of

less interest. The method elaborates statistical testing in the context of there being many potential types and commonly sparse data.

A second method used in the person-oriented approach is to identify a typology of developmental histories based on a variation of cluster analysis. The primary distinctive feature is the preliminary removal of aberrant outlier histories (Bergman, 1988, 1998), which, once dropped, allow for the recovery of much simpler and clearer cluster structures.

However derived, the typology of developmental histories identified is expected to provide insight in its own right and, by assigning individuals to types, can be used to consider the ways they also contrast with respect to other variables.

Discrete Combinatorial Pathways: Removing a Pathway and Attributable Fractions

For both practical and conceptual reasons, it would be very desirable to estimate what the impact would be of removing a component causal pathway. Of course, observing someone with depression does not reveal the pathway that was responsible, as even those exposed to CSA may develop depression by a mechanism not involving CSA. Among cases exposed to a particular risk, the attributable fraction of cases of depression produced by a particular risk exposure is estimated as

$$AF_e = \frac{(RR - 1)}{RR}$$

where RR is the causal risk ratio (or odds ratio, if the outcome is not too common). If we wanted to estimate the fraction of all cases, say among the CSA-exposed and -unexposed, that would not have occurred if there had been no CSA exposure, the population attributable fraction AF_p , this will depend on the proportion p of the population that are exposed:

$$AF_p = \frac{p(RR - 1)}{[p(RR - 1) + 1]}$$

Applied to the Wirral Women’s Health Study, these expressions yield estimates of RR of 4.29, $AF_e = 0.77$, and with 18.6% CSA-exposed, $AF_p = 0.38$. Can we interpret this as implying that if we were able to remove exposure to CSA the rate of depression would be reduced by 38%? Not necessarily.

First, those exposed to CSA may have elevated rates of exposure to other risk factors. We know that in the population, those exposed to CSA also have unusually high levels of childhood neglect, and removing their CSA exposure cannot automatically be expected to reduce their exposure to neglect. Some interventions might do that, but not all. We therefore need to adjust for the confounding effects of neglect. Walter (1976) shows how we can compose an adjusted AF_p as a weighted sum of the AF_p 's in strata k , $k = 1, K$ of the confounding factors, that is, $\sum_k w_k AF_{p(k)}$. Among the not-neglected stratum, the impact of CSA was very substantial, with an RR of 6.55 and $AF_{p(\text{not neglected})}$ of 0.42. Among the neglected stratum, the impact of CSA was much more modest, generating an RR of 1.35 and an $AF_{p(\text{neglected})}$ of 0.13. With neglect stratum population proportions of $w_{\text{not neglected}} = 0.71$ and $w_{\text{neglected}} = 0.29$, the adjusted population attributable fraction is 0.34. This corresponds to the estimated impact of lowering each of the two CSA-exposed arms in Figure 7.1 (one for the neglected and one for the not-neglected) to their corresponding neglect-similar but CSA-unexposed arms. Although adjustment for a second or even third confounder would be possible, for any adjusted population attributable fraction in a nonrandomized study there will always remain other possibly unmeasured confounders that could be included.

Second, an assumption has been made that removing the exposure has no other effects on the disposition and effects of other risks. Many policies designed to reduce CSA could be expected to reduce neglect as well, leading to larger reductions than expected, or might give rise to unintended breakup of family relationships, leading to smaller reductions than expected.

Thus, the practicality and seemingly simple interpretability of population attributable fractions as estimating the impact of closing off a pathway to some outcome should not be allowed to curtail critical thought.

Turning Points

The concept of a turning point can be seen as an elaboration of the idea of a pathway. It presupposes that there are forces at work that result in a substantial degree of predictability in the continuity of negative states or trajectories, but that there exist classes of event or experience that can perturb this. Turning points hold considerable intuitive appeal. They are the stuff of both much great literature and popular biography and autobiography and form the subject matter of much appealing qualitative research. However, for a more critical evaluation, turning points must satisfy a number of requirements.

The first is that it must be possible to gather data where the circumstances for a possible turning, the preconditioning event, have occurred and yet no turning event took place. This is the exact opposite of its popular and qualitative use that is entirely selective, identifying turning events and then asking subjects to nominate a temporally associated circumstance to which the turning event might be attributed. That approach can never disprove the causal role of any nominated preconditioning event.

But to gather data on preconditioning events regardless of whether they triggered a turning-point event or not requires a style of data collection that is much more closed. The set of potential preconditioning events must be known in advance such that it can be collected for those both with and without a turning-point event. Formally, it does not require a complete time diary of these preconditioning event occurrences, but almost so. Event histories are commonly analyzed using survival analysis methods, and here the conceptual logic behind the partial likelihood derivation of the Cox proportional hazards survival model is instructive (Cox, 1972). In this context, a Cox model would focus exclusively on the times at which turning-point events occurred and would consider the circumstances at that time of those who turned and compare them with the circumstances of those who could have turned but did not.

A second requirement is that the change brought about must have an impact that is not short-lived, but one that sets in train processes that sustain and support progress along the new path for an extended period. Thus, the event itself can involve a radical dislocation with the past, such as the move to a distant neighborhood that disrupted delinquency careers (West, 1982), but need not be so immediately life-transforming. The constructive role that a supportive partner can play (Quinton et al., 1993) is likely to owe more to the ongoing benefit in managing life's difficulties and opportunities than to a sudden charge of self-esteem (see also "Some Limitations of the Pathway Concept"). Nonetheless, the mechanism by which the precondition gives rise to the turning point should at the very least be theoretically elaborated and preferably empirically pursued and confirmed. However, as emphasized elsewhere in this chapter, the belief that effects can be transmitted across time through a sequence of steps, transitions, or links in a chain is not readily tenable unless there are some traits or persistent risk factors that are common to the operation of each step, inducing some correlation.

A third requirement is to properly consider the mechanisms that lead up to the occurrence of the preconditioning circumstances. This is necessary to characterize how dif-

ferent are those who experience the preconditioning event from those who do not.

A final important consideration is that turning points are often culturally specific. For example, one of the ways that negative turning points may have their effect is through “lost opportunities.” This may occur where access is restricted to a specific age at entry, as in many educational settings. Gaining or failing to gain access to some tier of education has therefore often been seen as a potential turning point. Recent changes in many countries to allow access across an extended age span may remove or modify such effects.

Mediation, Direct, and Indirect Effects

We have seen that one of the features expected of many conceptualizations of developmental pathways is the Markovian property. In the progression from A to C, if passage is mediated by B, then, having taken account of B, there are no direct effects of previous history. Illustrated in Figure 7.6, this technique matches with our intuitive notion of pathway in that the removal of the direct path from the causal exposure X to outcome Y leaves just the single pathway via Z. If $\Pr(Y|Z, X) = \Pr(Y|Z)$, then X is considered as having no direct effect on Y; its effects are mediated or are indirect through Z.

Baron and Kenny (1986) and Judd and Kenny (1981) describe four steps in investigating such mediation in SEM path diagrams: (1) Show that X is correlated with Y; (2) show that X is correlated with Z; (3) show that Z is correlated with Y; and (4) show that the effect (partial correlation) of X on Y controlling for Z is zero. In the regression framework, we would be comparing the regression of Y on X (model 1) and the regression of Y on X and Z (model 2). The estimated coefficients identify component pathways (see next section), and background effects due to possibly numerous other component causes are summarized within the error terms of the regressions. As commonly used, a

Figure 7.6 Direct and indirect effects.

significant coefficient for X in model 1, but a nonsignificant coefficient in model 2, is taken as evidence of mediation. Without further evidence, such a result could arise from Z being a confounder rather than a mediator, the association between X and Z implied as causal in the diagram in fact being merely correlational. Some difficulties in the use of this decomposition are discussed by Cole and Hernan (1998).

Where the focus is on estimating the direct effects of Z, the problem can also be viewed as one where the simple association of Z and Y is not an estimate of the causal effect of Z because individuals have been selectively assigned to or chosen nonrandomly their Z status. Adjustment for observed factors such as X that are correlated with Z can be made by use of the propensity score (Rosenbaum, 2002). Though not necessary, the theoretical arguments for the propensity score are typically based on the idea of counterfactuals—the outcome individuals would have experienced had they been exposed to a level of risk factor different to that which they did in fact, that is, had taken a path other than the one they did. For binary developmental state or exposure Z, the propensity score is the probability of Z as a function of the selection variables X, typically estimated as the predicted values obtained from a logistic regression with Z as outcome and X as predictors. Then matching, stratification, and covarying this estimated propensity in estimating the effect of Z on Y all provide a potentially valid means of estimating the causal association.

An interesting fourth approach, used in what Robins (Robins, Hernan, & Brumback, 2002) refers to as marginal structural modeling, is to use the propensity score as the basis of the calculation of weights. In the case where Z is binary, individuals with $Z = 1$ receive the weight $1/\text{propensity score}$, and those with $Z = 0$ receive the weight $1/(1 - \text{propensity score})$. In a sample weighted in this way, X and Z are uncorrelated, allowing the simple association between Z and Y to be interpreted causally.

Natural Experiments and Instrumental Variables

We reviewed earlier the compelling evidence that early adverse experiences in rodents and nonhuman primates have long-term behavioral and neuroendocrine consequences. The key features of these studies that make them relatively straightforward to interpret are that the depriving conditions were specified and manipulated experimentally and so were not correlated with any preexisting qualities of the parental animals, and that an adequate subsequent rearing environment could be guaranteed. Analogous experimental manipulation of the experiences of children is clearly out

of the question, and so alternative methods for attempting to identify whether there are early points of divergence have to be identified.

The majority of children grow up in families where there are strong continuities of relationships and parenting (e.g., Pianta, Sroufe, & Egeland, 1989), making the task of disentangling early and late effects more difficult. In the previous section, various adjustments for the possible measured confounding effects X on the estimation of the causal path $Z \rightarrow Y$ were presented. However, typically we can never be sure that there might not also exist unmeasured confounding variables, such as U in Figure 7.7. Their presence would prevent us from interpreting the association $Z \rightarrow Y$ as causal. The instrumental variable (IV) approach is capable of overcoming this limitation. This approach relies on there being a variable R , the instrumental variable, which is correlated with Z but that is known to have no effect on Y except through Z , that is, is entirely mediated through Z .

Then, in the simplest case of Z and Y being continuous, if in the regression of Y on Z we replace Z by the predicted value of Z obtained from the regression of Z on R , then the estimated effect is the causal effect of Z unconfounded by the unmeasured, even unmeasurable, effects of U .

The IV approach is clearly powerful, but finding suitable variables R is rarely possible in entirely observational studies. Many social experiments make use of the approach in so-called encouragement designs, in which a random subgroup are encouraged to participate in some program Z , the encouragement being designed to be sufficient to increase the proportion participating but not sufficient to in itself materially influence the outcome. Such a design and method of analysis is clearly suited to the evaluation of educational programs that may be cast in a developmental framework. In observational studies, instrumental variables are often identified either by the use of very strong

Figure 7.7 Controlling for unobserved confounder U by the use of an instrumental variable R .

theory, rarely as convincing to readers as it seems to be to authors, or by imaginative use of auxiliary data and of natural experiments. Administrative systems provide one common source. State intervention in child care has provided a number of opportunities for such investigation. Hodges and Tizard (1989) followed into adolescence a group of children who had experienced institutional care up to at least age 2, some of whom were then adopted and others returned to their families of origin, and compared them with adolescents who had not been exposed to institutional care. The family experiences of the adopted children were more advantageous in numerous respects than those returned to their own families, and this was reflected in their superior educational and behavioral performance. However, compared to the adolescents with no history of institutional care, the adopted children were overfriendly with strangers, they had more peer difficulties, and they were less likely to have formed close friendships. This suggests a long-term effect of institutional privation, not modified by later, potentially protective experiences. Rutter et al. (2001) provide other examples of natural experimental research opportunities.

Measurement Error in the Analysis of Developmental Pathways

Developmental models often focus on a single domain, analyzing repeated measures of some nominally comparability. This gives us the opportunity to examine critically a particular form of the direct and indirect effects decomposition. When we sketch out a model of development in which we have several pathways leading to some common node or developmental state, both our mental models and the pathway diagram immediately impose the Markovian assumption, suggesting that development beyond that node is independent of which pathway was followed in reaching that node. The alternative, less parsimonious model would require either additional paths from earlier periods of development or that the node for current developmental level be somehow disaggregated into a finer set of levels that are distinguished by developmental history (a higher-order Markov approach used with discrete variables).

Path Models and Latent Variable Model

The major advantage of the SEM approach is its ability, when applied to studies with suitable measurement designs, to tackle the problem of measurement error. Measurement error is ubiquitous and its impact often poorly understood.

TABLE 7.3 Summary Statistics from Longitudinal Cognitive Ability Study

	Age			
	6	7	9	11
Mean	18.03	25.82	35.26	46.59
Standard deviation	6.37	7.32	7.80	10.39

Age 7	.809			
9	.806	.850		
11	.765	.831	.867	

Source: "A Longitudinal Investigation of the Intellectual Differentiation Hypothesis," by R. T. Osbourne and D. E. Suddick, 1972, *Journal of Genetic Psychology*, 110, pp. 83–89.

This issue is well illustrated using the data of Osbourne and Suddick (1972) on the development of cognitive ability. This considers continuity between the ages of 6, 7, 9, and 11 years in a continuous measure of children's general ability. Summary statistics for data on 204 children are shown in Table 7.3.

As described in G. Dunn, Everitt, and Pickles (1993), a plausible starting model is the first-order autoregressive model shown in Figure 7.8 in which, in considering ability at one age, having taken into account ability at the previous measurement, there should be no association with any earlier measure. A feature of such a model is that an early measure may influence a later measure but only through an intermediate measure. The model consists of 3 regressions (Y2 on Y1, Y3 on Y2, and Y4 on Y3), but in addition to estimating the coefficients with standardized regression coefficients (.809, .850, and .867, respectively), SEM software also estimates a goodness-of-fit. In this case, a very poor fit is obtained, reflected in a chi-square of 61.82 with 3 degrees of freedom (10 observed summary statistics – 7 parameters: the variances for F1, E2, E3, and E4 and the 3 regression coefficients b_1 , b_2 , and b_3). This poor fit immediately tells us something is wrong. For many researchers, their instinct is to conclude that additional relationships must exist, for example, from Y1 to Y3 and Y2 to Y4.

Figure 7.8 Model with autoregression between observed cognitive scores.

Those additional relationships correspond to “sleepers effects,” that there is some part of a measure at one time that seems to have no effect on the immediately next measure but yet can influence the subsequent measure. There are circumstances where such effects are plausible (e.g., where the tests given have varying content and two tests far apart have a more similar content, say, being more mathematical). However, in general, more biologically based sleeper effects are frequently considered implausible. How can we improve the model fit without adding these sleeper effects?

One way is to take the issue of measurement error seriously. In the classical measurement error model, the observed measurement is related to a “true score” F and an additive measurement error E of constant variance, that is:

$$Y_i = F_i + E_i$$

The true score F is an example of a latent variable or factor, and in this simple case, one that involves no factor loading and is also therefore a simple random effect. Usually, replicate measurements are necessary to identify and estimate the measurement error separately from the true score. However, a structural equation model of the four measurements, graphically shown in Figure 7.9, can be fitted with constraints, enabling measurement error and true score variances to be identified with only single measurements per occasion. Imposing constraints such that the measurement error variance remains the same over the four occasions achieves identification of the model and involves only one more parameter than the previous model (3 regression coefficients between the factors and variances for F_1 , D_2 , D_3 , D_4 and the single common measurement error variance for the E s). Allowing for measurement results in a huge

Figure 7.9 Model with autoregression between latent “true-score” cognitive measures.

improvement in model fit, giving a well-fitting model with 2df goodness-of-fit chi-square of 1.43. Clearly, this model has no need of additional sleeper effects—it already fits so well. How has this come about?

In the model with regression among observed variables, measurement error in the predicting variable results in the estimated regression coefficient being attenuated, estimated as being smaller than it should have been in the absence of measurement error. This underestimation results in the predicted association among the most temporally distant variables, given by the product of the standardized regression coefficients $b_1 \times b_2 \times b_3$, being even more underestimated (a 10% underestimation in each coefficient resulting in a $1 - 0.9 \times 0.9 \times 0.9 = 27\%$ underestimation of their product). Allowing for measurement error corrects each regression coefficient and removes this gross underestimation of the model predicted long-term association.

There are important implications from this very modest example. The first is that although measurement error in a covariate X_1 may result in systematic underestimation of its relationship with some response, it can also give rise to overestimation of the effects of some other covariate, X_2 , with which X_1 is correlated. There are numerous reports that current health is not only associated with contemporaneous risk factors, but also independently with the same risk factors measured in childhood. Is this because the risk has its effect through an accumulation of risk exposure, or is it an artifact of measurement error in the contemporaneous measurements and that these contemporaneous measures tend to be correlated with childhood measures? This latter possibility is rarely explored.

Misclassification, Comorbidity, and Nonspecific Continuity

A common concern in psychiatry is the lack of specificity both of risk factors and in risk factor effects. Risk factors commonly raise risk for a wide variety of outcomes, and we find correspondingly high levels of comorbidity. Similarly, for many disorders, a current diagnosis raises rates for numerous future ones. Such poor specificity provides evidence against simple and distinct developmental pathways. However, just as measurement error hid the simple continuity model for ability, so classification errors in diagnosis could be masking much greater degrees of specificity.

In contrast to the numerous structural equation analyses of continuous measures, there are a meager number that have examined developmental pathways through discrete states that have accounted for misclassification, and probably none in a thoroughgoing fashion. The conceptual frame-

work for such models is latent transition modeling, in which the switching among states can be only indirectly observed. Pickles and Rutter (1991) considered a latent class transition model for the development of adult antisocial behavior from childhood. The model suggested that misclassification error substantially increased the apparent amount of change, that is, exaggerated levels of resolved childhood conduct problems and new-onset adult antisocial behavior. Accounting for that error suggested much higher rates of continuity. However, the association of this much-reduced level of change with putative turning-point events became all the more striking.

Growth Curve, Trajectory, and Mixture Models

Growth curve and trajectory models represent developmental processes with some pathway-like properties but that allow effects of history beyond the current state to influence likely future development. These models can be considered forms of multilevel, random effects or latent variable/SEM models (Raudenbush, 2001; Rogosa & Willett, 1985). In these models, an individual's path for the development of some feature is typically characterized by a baseline intercept and some slope for trend over time. Values of the intercept and slope vary from individual to individual but together form some bivariate random effect/latent variable distribution. In addition, allowance is made for occasion- and individual-specific disturbance, frequently thought to be made up largely of measurement error. With suitable repeated measure data, these individual intercepts and slopes can be estimated, allowing individual developmental trajectories to be calculated. Figure 7.10 shows a plot of such trajectories for the development of language for children with Autism, Pervasive Developmental Disorder, Not Otherwise Specified (PDD-NOS), and developmental delay (Taylor, Pickering, Lord, & Pickles, 1998).

Empirically, they can be considered as nothing more than a model-based smoothing of the raw observed language scores, but they are nonetheless useful for that. The top right plot shows clearly that the groups differ substantially on average. However, the remaining plots show that within each group there is substantial variation among individuals, with the result that there is substantial overlap among groups. This cautions us not to overstate the distinctiveness of the developmental pathways of each group.

A modification of the approach can also be used to identify homogeneity rather than heterogeneity. Instead of allowing individual trajectories to vary continuously with respect to intercept and slope, they can be restricted to a finite set of alternatives. This allows the estimation of a set

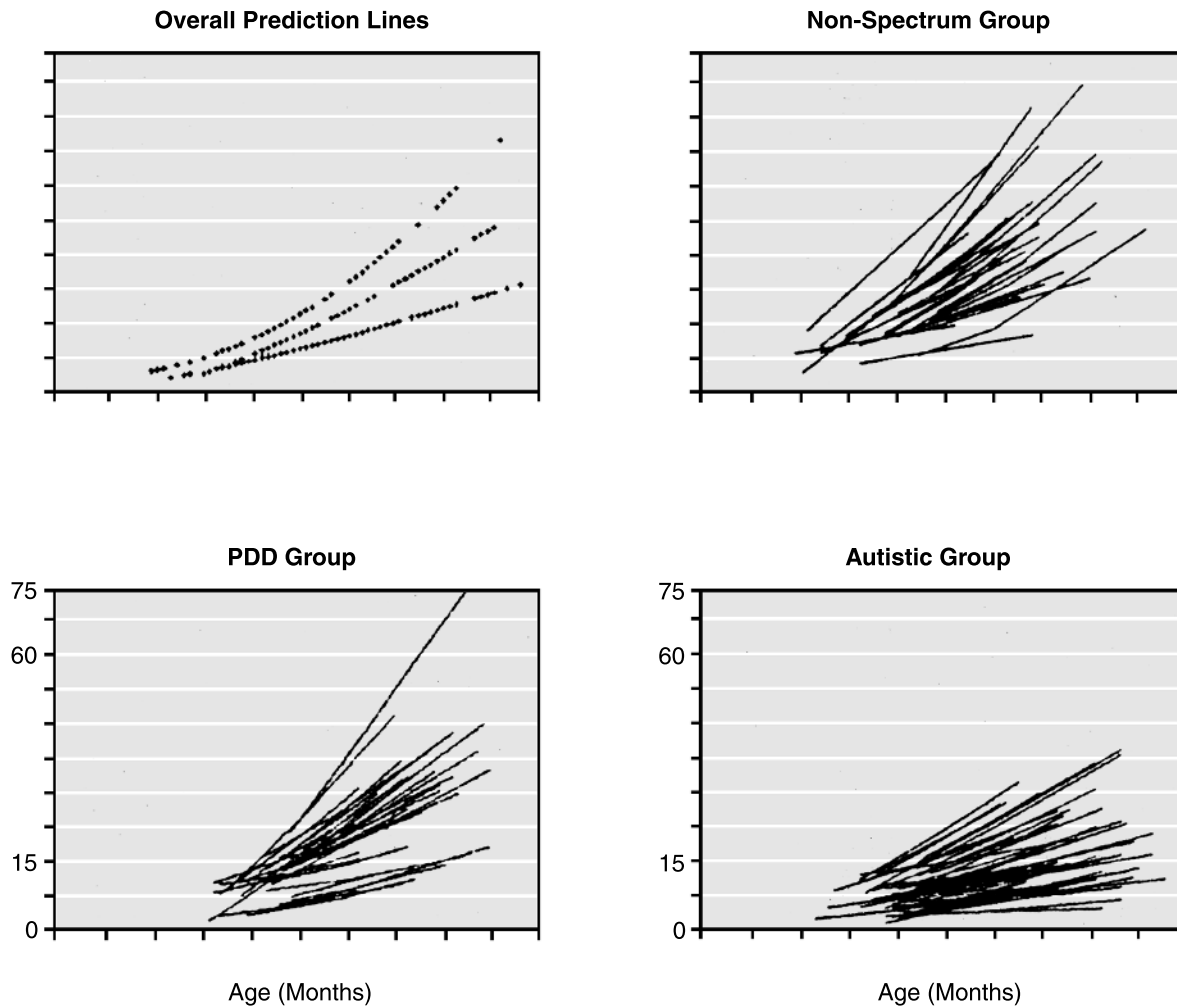

Figure 7.10 Estimated individual growth trajectories for children. *Source:* From “Mixed and Multilevel Models for Longitudinal Data: Growth Curve Analysis of Language Development” (pp. 127–144), by A. Taylor, K. Pickering, C. Lord, and A. Pickles, in *Recent Advances in the Statistical Analysis of Medical Data*, B. Everitt & G. Dunn (Eds.), 1998, London: Arnold.

of discrete developmental pathways with individuals having a higher or lower probability of belonging to each pathway. This kind of approach has been much used in criminology (e.g., D. F. Nagin & Tremblay, 2001).

From the perspective of SEM, these models can be seen as a restricted version of mixture covariance analysis (Muthén, 2001). In this approach, the underlying pattern of association among a set of continuous (latent) variables can themselves vary according to class, where class itself is a discrete latent variable. In an analysis of the development of drinking behavior using data from age 18 from the National Longitudinal Study of Youth and illustrated in Figure 7.11, Muthén and Muthén (2000) finds evidence for a normative pattern of development for 77% of the sample, where drinking rises from age 18 to a broad peak repre-

senting heavy drinking about once every 2 months until age 25, followed by a slow decline. A second class of 10% show rapid and continuous increase to the end of the period of study at age 30. A third class of 14% are already drinking heavily more than 3 times a month by age 18, but show continuous decline.

Moderator Effects

A moderator or effect modifier gives rise “to variation in the magnitude of a measure of exposure effect across levels of another variable” (Last, 1995, p. 254). This is most clear when Z changes the relationship between X and Y without directly influencing the level or probability of exposure to X. It suggests that Z somehow defines different

Figure 7.11 Mixture growth curve model of drinking behavior and dependence. *Source:* Adapted from “Second Generation SEM Growth Analysis” (pp. 291–322), by B. Muthén in L. M. Collins and A. Sayer (Eds.), 2001, *New Methods for the Analysis of Change*, Washington, DC: American Psychological Association.

subpopulations in which different causal chains operate. Terms like resiliency, susceptibility, and buffering factors may correspond to moderators. Early harsh, punitive, and hostile home environment predicted later victimization by peers, but only for children who had a low number of friendships; friendships acts as a moderating variable (where does this come from?). In this example, the moderation may be achieved contemporaneously, but where the impact of some risk experience can be carried forward in time through altered cognition or behavior, then moderation of the effects of that risk may occur at some point more distant in time.

Testing for moderation consists of testing for an interaction effect of risk and moderator on outcome, although, as we have described, care should be taken as to whether the appropriate null model is one of additive or multiplicative main effects (Tennant & Bebbington, 1978). For a pure moderator, we would also want to confirm the absence of any effect of the moderator in the absence of the risk exposure. Thus, in Brown’s (Brown & Harris, 1977) social causation models of depression, vulnerability factors, such as caring for multiple children under age 5, must not be associated with depression in the absence of the provoking agent of life events.

In latent variable modeling, moderation can be approached using multiple group analysis, where different paths may be allowed in moderator negative and moderator positive groups, or by the use of random coefficient models.

Developmental Pathways and Genes

The potential importance of genetics in the development of psychopathology is reflected in a burgeoning research ef-

fort into the identification of important genes and in estimating genetic contributions to variation in psychopathological outcomes. However, we often think about the effects of genes in a remarkably primitive fashion. We may have progressed from deterministic thinking, that the presence or absence of a particular allele at some locus may result in an unavoidable outcome, but for the most part, this has been replaced by a nebulous long-term stable propensity that gives rise to an expectation that the allele will increase the probability of the outcome. This fails to tackle the fundamental problem that must be overcome, one inadvertently perpetuated by the additive decompositions so fondly estimated by twin researchers, that of pitting nature *versus* nurture. The models that we entertain with respect to psychosocial variables are frequently complex and dynamic—they are developmental models. How do we integrate genetics into these models?

Genetic Contingency and Gene-Environment Interaction

Our discussion of causes made it clear that we often had to specify certain conditions or maintained hypotheses before we could expect to observe the effects of that cause. Exactly the same applies with genes and can provide one route to treatment. Thus, remove phenylalanine from the dietary environment and we do not observe the effects of the PKU gene on mental retardation. Improve childhood social environments and we may not see the effects of the MAOA gene on adult antisocial behavior.

Exactly where a genetically influenced pathway leads may be culturally mediated. Genes appear to be the major factor influencing variation in age of puberty. However, whether this leads to increased rates of incomplete education as a result of early-maturing girls associating with and leaving school at the same time as an older peer group appears to be culturally moderated. Traditional (less modern) societies may impose social controls that preclude such mixed-age association. More modern societies may allow forms of dating among young children, making association with older children unnecessary. The pathway from early puberty genes to incomplete education may operate only in the transition stage between traditional and modern societies. Of course, these same genes may now be associated with some new pathway to some other outcome.

Developmental Variation in the Importance of Genes

In the example just given, although genetic expression is environmentally contingent, the genetic vulnerability is perceived as time-invariant. However as we noted earlier,

animal studies have shown how gene expression can alter substantially in development, and often is under environmental control (Fish et al., 2004). Studies of human subjects suggest that the effects of different genes may follow different developmental timetables. Findings reported by the Specific Language Impairment Consortium (2002) from a genome screen for specific language impairment strongly suggested two genes associated with language impairment. However, these two genes were linked to quite distinct measures of language. One of these was a standard measure of expressive language in middle childhood; the other was linked to a measure of nonword repetition. This latter measure is thought to reflect a child's ability to learn a new word from a single hearing. This is an ability that would clearly be helpful, indeed perhaps the rate-limiting skill for the rapid expansion of vocabulary during the early stages of speech development. However, by middle childhood, all children have heard most of the words they need for everyday speech many, many times (hence the need to test this ability by the use of novel nonwords). Thus, this ability may no longer be the limiting factor in the use of language in middle childhood. Instead, perhaps some syntax-related skill limits language complexity, and it is this to which the second gene may be associated. This would be consistent with the genes having their effects on two distinct pathways to specific language impairment, one with early onset but with a substantial amount of subsequent resolution (as it does not constrain eventual vocabulary acquisition), whereas the other results in divergent development at a point where language structure is becoming more complex. Currently, this interpretation is little more than a hypothetical example, because we lack the necessary longitudinal data to be convincing, and more recent multivariate analysis questions the apparent specificity of early reports.

Gene-Environment Correlations

Plomin and Bergman (1991) elaborated how many apparent effects of the familial environment may in fact be the consequences of correlated and unmeasured genetic effects. This can arise in three ways: (1) passively, as where the child-rearing environment is influenced by parental genes that are inevitably correlated with child genes; (2) actively, as where children genetically predisposed to antisocial behavior may find themselves in unsupervised environments as a consequence of truanting; and (3) evocatively, as where children genetically predisposed to hostility can evoke negative reactions from their caregivers. Study designs able to account for such confounding effects of genes in examining environmental influences on development are

in principle little different from the more general problem of confounders already described, but they inevitably tend to exploit the natural experiment of mating and different kinds of sibship that arise.

FUTURE DIRECTIONS AND CONCLUSIONS

We have reviewed the conceptualization and the previous and current use of the developmental pathway term. But, how is it and its use likely to be developed in the future?

Future Directions

In some respects, the metaphor of developmental pathways has already been remarkably productive in the investigation of psychopathology. However, its full potential may not yet have been realized. It is commonly used as an innocuous summary term that allows researchers to convey the general area in which they are working. It becomes a tool with a more specific purpose when it is used to pose questions that might not otherwise be addressed, such as whether an outcome at one point in development is also a starting point for, and influence on, subsequent processes. However, it is uncommon for it to be employed to set up highly specific predictions, of the form "pathway theory would predict x, rather than y." For example, if there are multiple possible pathways, some more advantageous than others for long-term outcomes, and with genuine choice points, it follows that we should be able to identify phases in development around which future directions hinge. That means there should be other phases that are less pivotal. We reviewed earlier some of the evidence that this is indeed the case in the interplay among experience, neurobiology, and behavior. However, we have little idea how general this principle is over development. If it were more generally applicable, fascinating and important questions regarding mechanisms could be generated. A key issue would be, What are the mechanisms whereby at one time there is substantial instability and openness to external influences, and at other times considerable stability and an imperviousness to experience? In the case of the developing visual system or HPA regulation, it is plausible to suppose that there may be substantial periods over which gene expression is stable and impervious to environmental influences, punctuated by shorter critical phases of instability and sensitivity to the environment.

When we press the model in relation to psychosocial processes, it begins to set up interesting questions. The

transition from adolescence to adult life appears to represent a key phase over which there are branching points involving peer group, employment, and choice of romantic partner that have consequences that tend to be stable. The metaphor of the pathway suggests ways in which mechanisms might be conceptualized. Decisions at the branching point of a pathway may be made on the basis of the visible attractiveness of one pathway over another, making it desirable, for example, because the path has an exciting view, or because of features of the other paths that make them undesirable. Often, however, the immediate characteristics of the alternative pathways are less relevant than information about where the path leads. These considerations may be in competition; for example, one path is steep and difficult but leads to a fine restaurant, and the other is easy and pleasant but leads to a burger bar.

This suggests a program of work into the interplay between short- and long-term considerations in relation to, for example, education and relationships, in normal development starting in early adolescence, and into ways this is altered by individual differences, for example, in affect regulation. The pathway model would predict that normal development over adolescence is characterized by an increased use of long-term considerations in day-to-day behaviors, as a phase of pathway divergence approaches. It would also predict that, given the major negative implications of going down adverse pathways, the deployment of these longer-term considerations is generally not readily undermined by short-term considerations or emotional factors. Parents and peers may have a crucial role in ensuring the use of long-term considerations where there is a risk of this being undermined. An understanding of the normal or prevailing case could then inform the study of less advantageous or deviant pathways. For example, in relation to early adolescence, if the prediction is correct that the young person's behaviors are still determined mainly by short-term considerations, then if the young person has opportunities for sexual experiences, he or she will be vulnerable to making decisions about them that do not have a long-term perspective. This vulnerability will be further increased where parents and peers are not available to counter the use of short-term considerations. Later in adolescence, in some individuals the behaviors may still be dominated by features of the immediate landscape, or the use of long-term considerations may be readily undermined by emotional processes, such as strong attachment or sexual needs.

Used in this way, the pathway framework has the potential to bring particular questions into focus for study using a wide range of methods, including those that cur-

rently do not have a strong developmental emphasis. For example, theories of depression, discussed earlier, propose that vulnerable individuals have a heightened propensity to generate self-devaluative beliefs during periods of normal low mood. Techniques of study include eliciting beliefs during low mood induction, or simply by asking subjects about their thoughts during a recent time when they felt low. Experimental approaches informed by the pathway considerations reviewed here might similarly elicit cognitions about relationships with an emphasis on immediate and long-term considerations under varying conditions of affective challenge.

Another distinctive element of future research is likely to be the formulation of pathways that involve a much more complete elaboration across the various levels of explanation from neurobiology to cognitive psychology and on to psychosocial experience. We are beginning to see glimpses of the elements of such integrated pathways, most notably in the recent findings of gene-environment interaction (Caspi et al., 2003). However, each such pathway is likely to involve a very considerable research effort and will of necessity involve constructive interdisciplinary collaboration of a kind that is often fraught with difficulties. The elucidation of each will be exciting, but progress will be slow.

The pathways perspective also has implications for the way we conceive of outcomes in the evaluation of treatments. Ultimately, the goal of treatment is to reduce symptoms and impairment; however, this takes on a new complexion when considered in the context of developmental pathways. We reviewed earlier ways in which episodes of depression may influence pathways via effects on social functioning and cognitive processes. We do not, however, know whether treatment for depression also increases the likelihood of following a more advantageous pathway, nor whether treatments differ in this respect. Studies of differential treatment effects have been conducted. For example, Hollon et al. (2005) found that relapse rates in the year following cognitive therapy for depression were substantially lower than following medication. Follow-up informed by pathway considerations would also examine social, biological, and cognitive variables thought to influence risks for subsequent depression and other forms of psychopathology. In adolescence, improving the way choices with long-term implications are made, in the areas of education/work, peer group, and romantic partners, could have a greater impact on subsequent risk for psychopathology than treatments that bring about immediate symptomatic or functional changes.

Finally, the clinical implications of findings and concepts from pathways research are considerable. Overall, the

effect would be to draw attention in assessment to multiple aspects of functioning over considerable periods of time, instead of the more narrow focus on recent symptoms. More specifically, identifying key features of pathways to current psychopathology would provide the focus for treatment and suggest criteria for judging effectiveness. These may be quite distinct from symptomatic improvement. For example, substantial reduction in overall level of deviant behaviors with some antisocial adolescents may not be realistic, but promoting educational or vocational activities that have the potential to open new opportunities in the longer term may be crucial to their subsequent pathways. Therapeutically, the emphasis on a subset of difficulties with long-term implications, rather than on all of the young person's (often substantial) problems, also can lead to more modest and achievable treatment goals. Treatment strategies could also target ways of reducing the likelihood of behaviors that put a young person on a deviant pathway and increasing the chances of creating stable advantageous pathways. These might focus on cognitions associated with these behaviors and on processes that favor decisions associated with beneficial pathways, and on ways these may be undermined, for example, by attachment or sexual needs.

Conclusions

The use of the pathway metaphor has helped get the concept of developmental pathways into the common scientific vocabulary. Indeed, it is fair to say that the metaphor has dominated conceptualization, there being no widely shared definitions of the general concept of a developmental pathway that offer greater precision than the metaphor itself. Nonetheless, we have seen that a full and almost literal consideration of the metaphor reveals a quite remarkable number of detailed features, be they implications, qualities, constraints, or possibilities, that a developmental pathway should or could possess. It is in these last words where the major weakness of the concept is seen, in that there seems to be no identifiable set of features that are necessary for some longitudinal sequence of states, levels, and events to be referred to as a developmental pathway. We have seen examples of the use of the concept that in detail seem to share almost nothing. This finding mirrors how we use metaphors in our everyday language: to point to the presence of some feature rather than its absence.

But what a useful idea it remains! Indeed, one could argue that our mistake is that we have not pressed the idea to its limits. The richness of the metaphor provides us with a long list of thought experiments and hypotheses that need

to be addressed. Sometimes addressing these may be decisive in determining whether a pathway exists or not, such as determining whether A always precedes B which always precedes C. More often, however, addressing these will be informative about how the pathway is being conceived, which aspects of the metaphor are being highlighted as applying in this case, and thus sharpening our specific definition. If the developmental pathway concept is in its general form too unrestrictive, then in any specific case we must be clearer about which features apply and which do not.

We have also seen that even when we have identified the specific features that do apply to a specific case, the mechanisms that result in these features are the familiar mechanisms of biological and psychosocial development more generally. Developmental pathways add no new mechanisms. Instead, they provide a framework within which the action of several possibly fragmented processes can be combined, the mechanisms for each process being imported from elsewhere.

Can developmental pathways serve a useful, purely descriptive role, one in which it is intended that no causal attribution be made? Our instinct here is to say no. We illustrated examples, such as the growth curve models for language development, that are at one level little more than the smoothing of raw data, where description is clearly prominent. However, this was perhaps the example that drew least from the concept of a developmental pathway. In general, in defining developmental pathways researchers believe they are indicating causally important relationships. Thus, developmental pathways ought to have some consistent mapping to causal pathways and associated methods of analysis. It was clear that often the various formal, heuristic, and statistical causal pathway models each had something to contribute to our understanding, elaboration of prediction, and method of study of developmental pathways. But that is not to say that they were equivalent. Indeed, there is often a danger that one statistical representation of a pathway may be uncritically and inappropriately imposed on developmental data where another representation would be better suited.

The concept of a developmental pathway has been used in ways that have little in common and may even be mutually inconsistent, and has been haphazardly related to any causal model framework. Although in each case, further clarity and detailed elaboration should be sought, removing scope for confusion by restricting the concept to one particular formalization is probably not our recommendation. The major strength of the concept of a developmental pathway is as a device to stimulate the imagination and to

provide a framework for synthesis and integration. This we believe it does very well.

REFERENCES	281

A full understanding of the processes that lead to normal development and psychopathology requires a multifaceted approach that cuts across several specialties and disciplines. These disciplines range from molecular biology and neurophysiology to social psychology and behavioral ecology. The scope of research in these domains includes study of neural, perceptual, cognitive, social, and overt behavioral (action) processes. The conceptual integration of the rapidly emerging contributions from these fields of investigation present one of the greatest challenges in the biological and psychological sciences. Understanding the forces within the individual and in individual-environment trans-

action that drive the processes of self-organization within and across neural, perceptual-cognitive, and action systems adds another aspect to the challenge (Cicchetti & Tucker, 1994; Izard, Ackerman, Schoff, & Fine, 2000; Levinson, 1999; M. Lewis & Granic, 2000). In this chapter, we assume that the motivational processes associated with emotions are major players in self-organization within and across systems, in self-regulation, and in determining the adaptiveness of developmental trajectories. We take this position while remaining aware that a broad construct like self-regulation, often used in explaining the roots of psychopathology, requires research in attentional/cognitive

regulation and emotion regulation, as well as regulation at the neurobiological level (Calkins & Fox, 2002; Posner & Rothbart, 2000).

Many facets of normal development and functioning depend on the emotions and the brain and behavioral systems associated with them. For example, the social functions of emotions underlie attachment behavior and interpersonal relations (Panksepp, 2001), and the neural substrates of emotions play a pivotal role in memory and the motivational control of attention and cognitive processes (Cicchetti & Tucker, 1994; Tucker, 2001). Emotions serve a wide variety of functions that are critical to survival and adaptation, and they play a key role in goal-directed behavior (Campos, Mumme, Kermoian, & Campos, 1994; Darwin, 1872/1998; Izard, 1977; Lazarus, 1991). Thus, dysfunction in any of the emotion systems (e.g., interest, joy, sadness, anger, fear, shame, guilt) may contribute to the development of psychopathology.

The tendency of each basic emotion to motivate a particular type of cognition and action may be considered its executive function. Even in human suffering and psychopathology, emotions retain their executive function or inherent capacity to motivate adaptive cognition and action (Izard & Ackerman, 2000). Yet, person and contextual factors can alter this capacity and prevent its realization. Differences between emotion processes in normal and abnormal development relate primarily to the coordination of the components of emotion and to the connections among the emotion, cognitive, and action systems (Izard, 1979; Izard et al., 2000; Keltner & Kring, 1998; Kring & Bachorowski, 1999). Lack of coordination among emotion components (e.g., emotion arousal and feelings without emotion expression in Schizophrenia; Kring & Neale, 1996) and maladaptive intersystem connections (e.g., anger and shame linked to aggression and violence in delinquent youth; Baumeister, Smart, & Boden, 1996) help explain psychopathological processes and the role of emotions as causes and consequences of psychopathology. Poor intersystem connections tend to vitiate the inherently adaptive functions of emotions (Ackerman, Abe, & Izard, 1998).

Normative developmental tasks include laying the groundwork for coordinating emotion arousal, emotion motivation, and nonverbal and verbal emotion expression in the context of personality and social functioning (Abe & Izard, 1999a; Izard et al., 2000). Utilization of coordinated emotion system responding in adaptive behavior depends on the development of connections between the emotion, cognitive, and action systems (Ackerman et al., 1998; Izard, 2002). Without coordination among emotion components and effective intersystem connections, qualitative differ-

ences between normal and psychopathological development will occur in affective-cognitive structures or emotion-cognition relations and in emotion-thought-action patterns.

Coordination and regulation of the elements of an emotion system does not mean that all its components (neurobiological processes, subjective feeling, and expression) and the factors that contribute to its activation always follow a typical or set course (Ellsworth, 1994). Effective coordination of emotion processes sometimes depends on the intensity of the stimulus or emotion-eliciting situation and the way the executive functions of emotions play out in person-environment interactions. Sometimes the coordination of emotion system components depends, at least in part, on the executive functions of the cognitive systems. For example, it might prove quite adaptive to suppress the *expression* of anger *feelings* in response to provocative remarks by a person in authority or the expression of joy at that person's social blunder. This sort of interaction between executive functions in cognition and emotion processes depends on adaptive connections between the emotions and cognitive systems.

APPROACHES TO THE STUDY OF EMOTIONS AND PSYCHOPATHOLOGY

Two recent papers on the topic of emotions and psychopathology describe quite different approaches to this broad topic. They also testify to the rapidly growing body of literature concerned with the role of emotions in abnormal development and behavior.

An Approach Emphasizing the Social Functions of Emotion

In the first of these papers, the authors examined five categories of psychopathology in terms of the social functions of emotions (Keltner & Kring, 1998). The authors, along with a number of other theorists (e.g., Averill, 1992; Campos, Campos, & Barrett, 1989), assume that emotions represent adaptations to problems in forming and maintaining relationships. For example, emotion expressions elicit responses from others and play a part in coordinating aspects of social interactions, and emotion experiences gauge the significance of events and responses in social contexts. The authors maintain that emotions provide a wealth of information relevant to interpersonal interactions, conflict resolution, and social adjustment (cf. Forgas, 2002). Their perspective on emotions strongly suggests that disturbances in emotion experience or expression impact relationships negatively and contribute to various forms of

psychopathology. They argue that deficits in approach-related emotion systems or motivation for social contact contributes to depression, diminished emotion expressivity to the uncoordinated social interactions in schizophrenic individuals, heightened fear and diminished positive emotion to Social Phobia, and deficient emotion regulation to Borderline Personality Disorder (Keltner & Kring, 1998). Although some of these perturbations in emotion processes may affect an individual in a number of ways, researchers have placed emphasis on the problems created by deficits or limitations in the social functions of emotions.

In this chapter, we also examine the role of the social functions of emotions in psychopathology, but we place equal emphasis on intrapersonal functions of emotions, their role in motivating and organizing the thought and action involved in individual adjustment and personality development and functioning (Izard, 1993; Levinson, 1999). We consider emotion thresholds and the related construct of trait emotionality as examples of emotion-related personality factors or individual differences that may contribute to either normal or abnormal development, to resiliency or psychopathology (Fredrickson, 2000; Izard, 2002; Rothbart, Ahadi, & Evans, 2000).

A Dimensional Approach

In the second of these papers on emotions and psychopathology, the authors (Kring & Bachorowski, 1999) adopted a perspective that views emotions and their functions in terms of the two broad dimensions of approach and withdrawal, theory rooted in neuropsychological research (Davidson, 1992; Davidson & Tomarken, 1989; Gray, 1979, 1982, 1995). They suggest that the functions of emotions in persons with psychopathology remain comparable to these functions in normal individuals. Problems arise, in part, when deficits occur in any one of the components in emotion processes: "perception, experience, intensity, or display" (Kring & Bachorowski, 1999, p. 577). Disturbance in any one of these components can impair a person's "ability to achieve one or more emotion functions in an adaptive fashion" (p. 577).

Kring and Bachorowski (1999) discussed the relations of depression, anxiety disorders, psychopathy, and Schizophrenia to various disturbances in emotion processing and, in particular, to the hypothesized behavior activation and behavioral inhibition systems (Gray, 1978, 1995) and the conceptually similar approach and withdrawal motivation systems (Davidson, 1994). They review a substantial body of literature that suggests relations between various forms of psychopathology and these hypothesized systems. De-

pression relates to deficits in the approach motivation system (Depue, Krauss, & Spoont, 1987), anxiety disorders to disturbances in the withdrawal motivation system (Barlow, 1988; Gray, 1978), psychopathy to dysfunction in both the approach/behavioral activation system (strong) and withdrawal/inhibition system (weak), and Schizophrenia to problems in both the activation/approach systems and the inhibition/withdrawal systems (Fowles, 1994). Kring and Bachorowski note that a number of pathological conditions cannot be explained in terms of dysfunction in a single motivation system, a single dimension of emotionality, or a single component of emotion processes. For example, depression may include a combination of high negative affect and low positive affect, Schizophrenia a diminished emotion expression and possibly diminished emotion experience as well (Earnst & Kring, 1999), and psychopathy a discordance between emotion experience and its verbal articulation (Cleckley, 1941) as well as disjunction between components of the emotion process.

These reviews document the complex and highly significant role of emotions in psychopathology. Yet, they also leave room for additional approaches to understanding emotions as both causes and consequences of abnormal development. Keltner and Kring (1998) focused on the social functions of emotions. Much work remains in examining the role of emotion traits or emotionality as assessed in temperament and personality (Rothbart et al., 2000). Kring and Bachorowski (1999) organized their review in a framework of affective dimensions, and they leave open a number of issues relating to discrete emotions. Each of the two papers examined a half-dozen categories of psychopathology, all of them largely in relation to research on adults. The authors of these reviews were not always able to find unique emotion characteristics or emotion-related cognitive or behavioral correlates for each diagnostic category. This apparent lack of disorder-specific emotion features may reflect the underlying dimensional nature of psychopathology, the fuzzy boundaries between the criteria that attempt to separate categories of psychological disorders. It may also reflect the need for further study of emotion processes in abnormal behavior. In any case, insofar as we are unable to relate aspects of emotion system functioning or malfunctioning to particular mental health problems, we leave a challenge for future research and analysis.

The Present Approach to Understanding the Role of Emotions in Psychopathology

In this chapter, we review the emotional aspects of psychological disorders and attempt to find new links between

emotion processes and psychopathology. We align emotion systems functioning and nosological categories in ways not emphasized in previous reviews of the relations of emotions to psychopathology. First, we consider systematically both the individual and social functions of emotions. We recognize that these two types of functions do not constitute orthogonal sets of emotion characteristics. However, some functions of particular discrete emotions apparently have more direct influence on personality or individual functioning than on social functioning (e.g., individual- or self-oriented shame motivation toward self-improvement; Tomkins, 1963). Moreover, consideration of individual differences in emotion thresholds or trait emotionality should help in discussing the related constructs of temperament and personality as factors in the development of psychopathology (Schultz, Izard, & Bear, 2004). Such discussions would complement explanations of psychopathology based on emotion processes that are more strongly influenced by contextual factors. Although some of the effects of an emotion threshold on an individual's adjustment or adaptation may appear in both social and nonsocial contexts, emotion thresholds that help determine characteristic mood and levels of positive and negative emotionality clearly relate to normal and abnormal personality functioning (Izard, Libero, Putnam, & Haynes, 1993; cf. Watson & Clark, 1992).

Yet, one could reasonably speculate that an abnormally high threshold for the emotion of interest-excitement might tend to preclude or greatly diminish sustained constructive endeavors or exciting activities of any sort, including social interactions. Such a lack of engagement in the environment characterizes those suffering an episode of Major Depression (Cicchetti & Toth, 1995). The behavior of depressive patients suggests that they also have an abnormally high threshold for enjoyment-joy. The consequent lack of joy experiences reduces feelings of self-confidence and self-worth and tends to diminish social interactions (Izard, 1977; Marshall & Izard, 1972). Higher levels of the emotions of interest and joy are associated with higher levels of extroversion or sociability (Izard et al., 1993). Thus, the effects on personality functioning stemming from this pattern of thresholds for positive emotions could have a strong impact on social functioning.

Second, we see if attention to the functions of discrete emotions (Frijda, 1986, 1994; Izard, 1989; Izard & Ackerman, 2000; Plutchik, 1980; Tomkins, 1962, 1963) can add to our understanding of psychopathology in terms of different but related sets of broad affective dimensions: positive and negative emotionality (Watson & Clark, 1992), behavioral activation and inhibition systems (Gray, 1995), and

approach and avoidance motivation systems (Davidson, 1992). We also review evidence relating specific emotions and patterns of emotions to psychopathology. In pursuing the discrete emotions approach to understanding the development of psychopathology, we consider three overlapping facets of emotion processes: the organizational and motivational functions of discrete emotions, their developmental functions, and their effects on personality and social functioning.

Finally, we discuss several topics relating discrete emotions theory and research to psychopathology that researchers have not dealt with or emphasized in previous reviews. Here, we briefly define these topics; later, we use them to guide our discussion of several types of psychological disorders.

The Developmental Functions of Emotions

Clearly, certain emotions are more prominent in one period of development than another, and these stage-salient emotions serve adaptive functions (see Abe & Izard, 1999a, and Izard, 1991, for reviews). For example, healthy young infants stimulate growth-inducing social interaction and gain social support by smiling readily and frequently and at virtually anyone who enters their perceptual field. On the other hand, if stage-salient emotions become dysregulated, either under- or overregulated, they become dysadaptive and can lead to psychopathology. For example, high-intensity and frequent expressions of anger and sadness in toddlerhood relates significantly to the trait of neuroticism at age 3.5 years (Abe & Izard, 1999b).

Emotion-Cognition Relations

In recent years, neuroscience has greatly increased our understanding of both the modular and interactive output of the brain systems underlying the emotions and various types of cognitive processes (Bechara, Damasio, Tranel, & Damasio, 1997; Damasio, 1994, 1998, 1999; Davidson, 1992; LeDoux, 1996; LeDoux, Romanski, & Xagoraris, 1989). For example, the evidence indicates that brain systems can generate and sustain emotional behavior in the absence of any cognition other than perceptual discrimination (LeDoux, Sakaguchi, & Reis, 1984). Yet, critical questions about some of the basic processes remain unanswered: What is the significance of modular and relatively independent functioning of the emotion systems? Are there individual differences in modularity, perhaps in children at risk for Autism or Schizophrenia, that suggest the need for more attention to the development of emotion-cognition relations (Simons, Fitzgibbons, & Fiorito, 1993)? What is the nature of the perceptual, cognitive, or information-processing bias

that characterizes aggressive children, psychopathic youth, and adults with anxiety disorders (Crick & Dodge, 1994; McNally, 1996; Schultz, Izard, & Ackerman, 2000)? Does such a bias signal dysfunction in brain systems concerned mainly with perception, cognition, and information processing associated with rational decision making? Does it represent a deficit in emotion systems and emotion information processing (Schultz et al., 2000)? Or does it signal problems in both emotion systems and cognitive processes, as well as in emotion socialization?

The development of emotion-cognition relations can be studied using “experiments in nature” (see Cicchetti, 2002). Such studies can be found in the research on children with Down syndrome, autistic people, and children who have experienced maltreatment. Both children with Down syndrome and children who experienced maltreatment use fewer words to express internal states, including words referring to emotion in self and other. The ability to express verbally one’s own and others’ feelings is considered a hallmark of early emotional development and a predictor of later social competence (Denham, 1998; Izard, 2002). In normally developing children, internal state language correlated with play behaviors, but this relation did not hold for the children with Down syndrome (Beeghly & Cicchetti, 1997). These findings suggest that intersystem connections emerge between cognitive-language abilities and socioemotional regulatory behaviors for normally developing children. These connections may be delayed and diminished for children with Down syndrome. Similarly, Autism may be characterized by a dissociation between emotion and cognition, whereby cognitive “systemizing” dominates and empathetic processing is less prominent (Baron-Cohen, 2003). This dissociation is particularly evident in brain imaging of people with Autism during an emotion recognition task. Brain regions involved in cognitive processing (i.e., temporal lobes) show increased activation, whereas emotion-processing regions (i.e., amygdala) show decreased activation (Baron-Cohen et al., 1999).

These experiments in nature suggest that the emergence of intersystem connections between emotion and cognition is a hallmark of normal emotional development. When these connections fail to develop, problem behaviors are likely to emerge, even for children without developmental disorders. The link between poor intersystem connections and emerging psychopathology is particularly relevant for children raised in abusive and impoverished environments. Children who experience abuse show abnormal emotion-processing patterns and sensitivity to anger that may prove adaptive in the home environment but is maladaptive in other contexts (e.g., peer interactions at school; Pollak, Cicchetti, Klor-

man, & Brumaghim, 1997). The delayed development of internal state language may further compound maltreated children’s problems as frequent experience of negative emotion and sensitivity to anger cues do not cohere with the cognitive ability to communicate these experiences verbally (Beeghly & Cicchetti, 1997).

Emotions, Culture, and Socialization Processes

We expect cultural factors and socialization to affect the way that emotions influence the development of psychopathology and the emergence and meaning of symptoms. Appraisals that lead to emotions, attitudes toward emotions, emotion labels, emotion concepts, and emotion expressions vary across cultures (Izard, 1971; Markus & Kitayama, 1991; Matsumoto, 1990), and these differences may cause variations in the relations between emotions and psychopathology. A certain set of symptoms leads Chinese psychiatrists to diagnose a patient as psychasthenic, whereas a very similar set of symptoms and underlying biochemical changes lead American psychiatrists to diagnose the patient as depressive. Although in the biomedical framework these are interchangeable diagnoses, a highly persuasive set of arguments based on cultural psychology suggests that psychasthenic patients in China have different affective-cognitive structures and suffer in significantly different ways from depressives in the United States (Shweder, 1988). Within cultures, variations in socialization practices result in individual differences in children’s ability to express and regulate emotions, and socialization involving extreme forms of parent-child interactions like abuse or maltreatment may impede emotional development, alter neurobiological stress-response systems, and increase the likelihood of psychopathology (Cicchetti, 1990, 2002; Cicchetti & Rogosch, 2001a, 2001b; Shipman & Zeman, 2001).

Expressing Emotion

As early as infancy, individuals begin to develop a characteristic style of expressing emotions, and the frequency of expression of various discrete emotions tends to remain stable over time (Hyson & Izard, 1985; Izard, Hembree, & Huebner, 1987). Expression styles in toddlerhood predict expectable personality characteristics, including neuroticism, at age 3.5 years (Abe & Izard, 1999b). In later development, some aspects of emotion expression relate to many forms of psychopathology. We see attenuated or discordant expression in people at risk for Schizophrenia (Simons et al., 1993), prolonged expression of negative emotions (particularly sadness and anger) in depression (Blumberg & Izard, 1986), dampened or developmentally delayed ex-

pression in Down Syndrome Disorder (Cicchetti & Sroufe, 1976; Emde, Katz, & Thorpe, 1978), inappropriate or incongruous expression in Autism (Sigman & Capps, 1997), and deceptive expression in psychopathy (Cleckley, 1941; Patrick, 1994). Furthermore, expressions of particular emotions in certain conditions characterize aggressive rejected children (Hubbard, 2001) and delinquent youth (Keltner, Moffitt, & Stouthamer-Loeber, 1995) and may reveal the type of abuse that leads to a Posttraumatic Stress Disorder (Bonanno et al., 2002).

Emotion Patterns

Provocative situations, whether real or imagined, typically elicit a pattern of discrete emotions, and different patterns of emotions characterize some psychological disorders. Patterns of emotions are particularly evident in anxiety and depression (Izard, 1972; Izard & Youngstrom, 1996). Understanding such patterns of emotions and the implications of co-occurring emotions for emotion regulation and emotion motivation should help in understanding and treating emotions-related problems (Izard, 2002) and in discerning the roots of some forms of psychopathology.

Emotion Knowledge: Its Role in Emotion Communication, Empathy, and Adaptive and Maladaptive Behavior

Emotion communication plays a key role in social interactions and the development of the attachment bond and other relationships (Ainsworth, Blehar, Waters, & Wall, 1978; Bowlby, 1969, 1973; Hobson, 1995). Before children acquire language, emotion communication depends on facial, vocal, and postural cues in expressive behavior (Izard et al., 1995; Zivin, 1986). Soon after the beginning of language acquisition, children use words to label and talk about their own and others' feelings (Bretherton & Beeghley-Smith, 1982), and the verbal component of emotion communication grows steadily in early childhood (Dunn, Bretherton, & Munn, 1987; Izard, 1971).

Both before and after language acquisition, effective emotion communication depends on the ability of the participants to detect and respond in a meaningful fashion to each other's emotion signals. After language acquisition, both accurate emotion perception and emotion labeling become critical in emotion communication and essential to empathic responding and prosocial behavior. These emotion-related skills form the foundation for emotion knowledge (Izard, 2001) and the construct of emotional intelligence (Mayer & Salovey, 1997). Deficits in emotion knowledge are associated with low socioemotional and academic competence (Denham, 1998; Izard et al., 2001)

and with internalizing behavior (Fine, Izard, Mostow, Trentacosta, & Ackerman, 2003).

Emotion Regulation and Dysregulation

Researchers view emotion regulation and attention regulation as the critical components of self-regulation, the key to adaptive psychological and neurobiological functioning (Calkins & Fox, 2002; Posner & Rothbart, 2000). Current theory and research indicate that the study of each of these three broad interrelated constructs requires a multilevel approach that considers processes at the neural, emotional, and cognitive levels (Cicchetti & Dawson, 2002).

A large body of literature attests to the significance of emotion regulation for adaptive behavior and the role of emotion dysregulation in maladaptive behavior and psychopathology (Cicchetti & Rogosch, 2001a; Eisenberg et al., 1995; for a review, see Eisenberg, 2000; Eisenberg, Fabes, & Losoya, 1997). Trauma, in the form of socioemotional deprivation, significant negative life events, or child maltreatment, often leads to emotion dysregulation and psychopathology (Cicchetti & Lynch, 1995; Cicchetti & Rogosch, 2001b). Inability to regulate emotions may preclude empathic or prosocial responding (Eisenberg et al., 1996), a condition that may characterize a number of psychological disorders.

EMOTION REGULATION AND DYSREGULATION AND PSYCHOPATHOLOGY

Emotion regulation is central to normal development, and poor emotion regulation or dysregulation is a key factor in the development of psychopathology. The prominent role of emotion regulation and dysregulation in normal and abnormal behavior may become clearer when we consider the number and complexity of the relevant systems or components that contribute to the management of emotions.

Several widely cited and quite useful definitions and treatments of emotion regulation explain it largely in terms of a combination of cognitive, behavioral, and social processes (Folkman & Lazarus, 1990; Kopp, 1989; Thompson, 1994; Thompson & Calkins, 1996). A researcher's emphasis on one or more of these three types of regulatory processes depends on his or her definition of emotion. For example, when researchers define emotions as cognition-dependent phenomena, they focus on processes involved in the deployment of attention, reinterpretation of the eliciting event, and actions that change the meaning of the person-environment relationship

(Folkman & Lazarus, 1990). For the most part, approaches to emotion regulation that focus on cognitive, behavioral, and social processes have addressed issues relating to socioemotional competence and adaptive behavior. They usually do not deal specifically with the role of emotion regulation in psychopathology.

A few researchers concerned with emotion regulation have recognized that it entails a multiplicity of systems and domains of functioning (Cicchetti & Tucker, 1994; Izard & Kobak, 1991). They suggest that the key components of emotion regulation include neurobiological systems, traits of emotionality/temperament/personality (e.g., emotion thresholds), cognitive processes, interpersonal relationships, and intersystem interactions and connections. They recognize different types of regulatory processes. Some of the processes of emotion regulation proceed more or less automatically and preconsciously (e.g., changes in brain and neural systems that influence emotion activation thresholds and responses to stress). Other processes of emotion regulation, like those dependent on executive functions of emotions and cognition, occur in consciousness or can be accessed reflectively.

Executive functions of emotions consist of their inherently motivational and goal-oriented qualities, which may include action tendencies. All of these characteristics of emotion and the way they play out in person-environment transactions affect emotion regulation. Executive functions of cognition as it relates to emotions consist of attentional control and consequent appraisal and attributional processes that activate a particular emotion and decision-making processes relating to coping strategies (Posner & Rothbart, 2000). These processes help determine the initial emotion response to a given event or situation and monitor the appropriateness of the emotion for a particular context. Hence they have direct implications for emotion regulation.

The factors governing emotion regulation are an interrelated set of modular systems. Each has some separate functions, and each may have a significant influence on the other. We review these regulatory systems briefly here and note some of the ways they relate to psychopathology.

Neurobiological Processes in Emotion Regulation and Psychopathology

Virtually any neurobiological system may affect emotion regulation. We examine three that play critical roles: the prefrontal cortex (PFC), particularly as it relates to other regulatory systems; the hypothalamus-pituitary-adrenal (HPA) system; and the vagal (Xth cranial) nerve complex

(VC) of the autonomic nervous system (ANS). All three of these systems are influenced by fundamental mechanisms of self-regulation mediated by the neurochemically specific pathways (e.g., norepinephrine, dopamine, acetylcholine, serotonin) that project from the brain stem (Cicchetti & Tucker, 1994). All three of the systems, as modulated by fundamental neurochemical processes, appear to have the capacity to influence the threshold and intensity of emotion arousal.

Much of the research on the regulatory functions of the PFC, the HPA system, and the VC has focused on the broad construct of stress and responses to stress. (An exception is the recent conception of the VC as the neural basis of the social engagement system; Porges, 2001.) Although stress undoubtedly involves negative emotions, the extant research rarely makes it possible to identify stress-response processes related to a particular emotion or pattern of specific emotions. Even when researchers can specify whether the emotions involved are approach or avoidant in nature, they still may not find it possible to identify discrete emotions (Davidson, 1998). Nevertheless, studies that attempt to relate the functioning of these major regulatory systems to dysadaptive behavior and psychopathology have implications for the regulation and dysregulation of discrete emotions.

Emotion Activation and Regulation: The Prefrontal Cortex and Amygdala

The PFC is central to adaptive functioning, and understanding of its functions seems necessary to advance the science of psychopathology. The PFC plays a critical role in processing emotion information and regulating emotional responding and in the executive functions of cognition (Damasio, 1994; LeDoux, 1996; Posner & Rothbart, 2000). It is also involved in the regulation of the VC and the HPA systems. Effects of damage to the PFC highlight its role in the executive functions of cognition. Researchers compared the performance of patients with lesions in the ventromedial area of the PFC with normal controls on a task involving risk-related decisions (Bechara et al., 1997). The investigators measured the behavioral effects of participants' decisions as they proceeded through the task and also recorded their emotional (skin conductance) responses. The patients with damage to the ventromedial PFC did not respond emotionally to task activities, and thus nonconscious internal emotion signals failed to protect them from risky decisions. In contrast, the normal patients showed conditioned emotional responding to high-risk activities, and internal emotion signals enabled them to perform adaptively on the task.

Recent reviews (Herman & Cullinan, 1997; Sullivan & Gratton, 2002) of studies of the neurocircuitry of stress (interpretable as negative emotion) make it clear that the PFC exerts control over the highly interactive HPA and VC systems. Thus, the PFC, through its connections to the HPA and VC, influences neurophysiological responses to stress and threat (Herman & Cullinan, 1997), as well as to positively toned social stimuli (Porges, 2001). The PFC projects directly to the hypothalamus, which initiates activity in the HPA system and the release of glucocorticoids that facilitate adaptive responses to stress. (The HPA system regulation is also strongly influenced by the hippocampus; Herman & Cullinan, 1997.) The PFC's control over the generative aspects of these neural systems for responding to affective stimuli shows that it is intricately involved in emotion regulation. The PFC and its relations to the HPA system and the VC definitely have implications for a number of psychopathological conditions (Sullivan & Gratton, 2002).

Although the neocortex is normally involved in emotion information processing, emotion regulation, and emotional responding, emotions can occur without benefit of the regulatory functions of the PFC. This is probably particularly so when the individual perceives dangerous stimuli that can elicit an adaptive response after only minimal processing. Using animal models, LeDoux (1996) and his colleagues (LeDoux, Sakaguchi, Iwata, & Reis, 1986; LeDoux et al., 1984) and Davis and his colleagues (Campeau & Davis, 1995) have demonstrated that fear conditioning can occur through a subcortical route. Fear behavior can emerge without input to or output from the relevant region of the neocortex and thus without benefit of accompanying higher-order cognition and its influence on coping strategies. In this subcortical activation process, emotion occurs rapidly, automatically, and unconsciously and therefore makes immediate and distinct demands on regulatory systems.

LeDoux (1996) has described the thalamo-amygdala circuit for information processing and emotion activation as the "low road" to emotion. When emotion responses are learned through this pathway, they tend to make indelible memories that resist extinction (LeDoux et al., 1989). Other studies have shown that repeated stimulation (kindling) of the amygdala lowers the threshold for the activation of emotion and increases the likelihood of increasing its intensity and duration and creating chronic anxiety (Rosen & Schulkin, 1997). Researchers have also observed kindling-like processes in depressive patients, suggesting experienced-based lowered emotion thresholds (Cicchetti & Toth, 1995). Repeated stimulation or kindling of the

amygdala and possibly other limbic structures changes emotion thresholds, suggesting that the neural substrates of emotions may have their own emotion regulatory functions that can be adversely affected by the social and physical environment (Cicchetti & Tucker, 1994; Rosen & Schulkin, 1997).

Research from multiple laboratories indicates that the amygdala is an effective mediator of emotion activation, and findings from research on emotion activation with animal models may generalize to human beings (Rosen & Schulkin, 1997). Evidence for such generalization came from a study in which investigators compared neurological patients who had bilateral damage to the amygdala and patients who had bilateral damage to the hippocampus, a structure critical to memory and to emotion-cognition interactions (Bechara et al., 1995). In an auditory conditioning experiment, the brain-damaged patients and a normal control group were shown a sequence of colored cards in which the green one (conditioned stimulus) was followed by a blast of a nearby ship's horn (unconditioned stimulus). Emotional response was measured in terms of the skin conductance response (SCR). The patients with bilateral damage to the amygdala did not show an elevated SCR, but they remembered the colors of the cards and other declarative information about the experiment. The patients with bilateral damage to the hippocampus showed an elevated SCR (emotional response), but they did not remember declarative information about the experiment. The control patients showed both an elevated SCR and good memory for the details of the experiment. Current evidence suggests that the amygdala may play a role in evaluating the significance of emotion-related stimuli regardless of their valence (Davidson, Pizzagalli, Nitschke, & Putnam, 2002).

It does not take trauma or injury to change brain structures and functions (Greenough, Black, & Wallace, 1987; Rosen & Schulkin, 1997). Negative life events and a number of factors in harsh environments may produce experience-based changes in brain and neural processes and thereby contribute to under- or overregulation of emotions and consequent psychopathology. In contrast, frequent positive emotion experiences contribute to the development of empathy, moral reasoning, and other aspects of adaptive behavior (Kochanska & Murray, 2000).

In summary, the PFC normally exercises considerable control over emotion and responses to activating stimuli. In the intact individual, both the PFC and the amygdala participate in the information processing that leads to emotion and coping responses. Emotional learning and responding without benefit of PFC serve immediate survival functions but have serious limitations for long-term adaptation. The

PFC is central among the neocortical structures that provide the neural substrates for the executive functions of cognition that govern the conception, planning, and performance of coping strategies.

The Vagal Nerve Complex

The VC is that part of the parasympathetic branch of the ANS that modulates activity of the visceral organs. Of particular importance to the self-regulation of emotion and behavioral adaptation, the tonic firing of the vagus nerve slows the cardiac and respiratory systems and influences the voluntary regulation of the muscles of facial and vocal expression of emotion. Although high basal vagal tone relates to adaptive attentional, cognitive, and behavioral functioning (Porter, Porges, & Marshall, 1988), the ability to both enhance and suppress vagal tone may prove adaptive in responding to different forms of stress or challenge (Porges, Doussard-Roosevelt, Portales, & Greenspan, 1996). The VC has been conceived as the neural underpinning of the social engagement system and as a system that may be changed by early experience (Porges, 2001).

A rapidly increasing number of studies have shown that the parasympathetic nervous system (PNS) and its control by the vagus (Xth cranial) nerve figures significantly in emotion regulation. In particular, research supports the hypothesis that vagal control of the heart and especially heart rate variability (indexed in terms of vagal tone) has direct relations to emotion regulation and coping ability (Porges, 2001). The relations between vagal tone, emotion regulation, and adaptation suggest that dysfunction in the PNS or VC may play a prominent role in the development of psychopathology.

Baseline vagal tone relates to both soothability and behavioral reactivity. It also tends to be associated with ability to focus attention and self-soothe, evidence of its role in emotion regulation (Porges, 1992). Infants with low basal vagal tone and an inability to suppress vagal activity have more behavior problems during the preschool years (Porges et al., 1996). Parental emotion coaching may influence basal vagal tone, which in turn predicts various behavioral outcomes, including child health and peer relations (Gottman, Katz, & Hooven, 1996). Vagal tone, like other indexes of emotion regulation, increases with age (Izard, Porges, et al., 1991).

The Hypothalamus-Pituitary-Adrenal System

Researchers identify the HPA system as a critical neurobiological system for responding to and coping with stress (De Kloet & McEwen, 1976; Sapolsky, Krey, & McEwen, 1986). The HPA system appears to have an especially important

role in responding to processive stress or stressful events or conditions that require interpretation by the PFC or other higher brain structures (Herman & Cullinan, 1997).

Stress activates the HPA and the release of cortisol and other glucocorticoids by the adrenal gland. These neurobiological changes prepare the individual for defense and coping. However, person traits and person-environment transactions, particularly experience in difficult or harsh conditions, may lead to hypersecretion of glucocorticoids. Hypersecretion can lead to illness and psychopathology, including hypertension, affective disorders, and Posttraumatic Stress Disorders (Herman & Cullinan, 1997). The HPA system can be modified by early experience, and resultant changes in its structures and functions figure in the development of psychopathology (Gunnar & Donzella, 2002; Suomi, 1991).

Since the early work of Kagan and his colleagues (Kagan, Reznick, & Snidman, 1987), a growing number of researchers have shown important relations between the HPA system, emotion regulation, and adaptation. In general, this research shows that higher average cortisol levels are associated with internalizing and withdrawal behavior (and probably underlying emotion responses including shyness or fearfulness; Kagan, 1998). Lower average cortisol levels were associated with both positive and negative approach behaviors (e.g., Smider et al., 2002). However, in clinic-referred school-age boys, low cortisol levels (averaged across two time points taken 2 years apart) were associated with early onset and persistence of aggression (McBurnett, Lahey, Rathouz, & Loeber, 2000; cf. Cicchetti & Rogosch, 2001b).

Neurobiological Regulatory Systems, Brain Asymmetry, and Psychopathology

The interrelations among the PFC, HPA, and VC make it difficult to specify their separate roles in causal processes that contribute to psychopathology. Moreover, psychopathology that has precipitating factors in the environment or in person-environment transactions may, in turn, have adverse effects on the functioning of neurobiological systems (Greenough et al., 1987). Another factor in the relations of these systems to psychopathology apparently derives from brain hemisphere asymmetry (Davidson, 1994; Davidson, Marshall, Tomarken, & Henriques, 2000). Some individuals exhibit functional asymmetries, and a right hemisphere bias appears to have quite different implications for adaptation than does a left hemisphere bias.

A recent review (Sullivan & Gratton, 2002) revealed a number of relations between differential functioning of the brain hemispheres, neurobiological systems, and psycho-

pathology. Left-biased PFC activity is associated with positive emotion and approach behavior. Right lesions to the PFC suppress stress-induced HPA activity and corticosterone responses and result in anxiety. Excessive right PFC activity appears to be a trait-like characteristic of highly anxious people, who may become predisposed to a number of stress-related psychopathologies that relate to chronic high levels of glucocorticoids. Right bias predisposes people to shyness, withdrawal, and defensive behavior. Withdrawal behavior, depression, and anxiety are also associated with increased HPA activity, chronic elevations in basal cortisol, and deficient feedback regulation. However, depression appears to be related to left-sided PFC hypo-function (at least for women; A. L. Miller et al., 2002) and anxiety to right-sided PFC hyperfunction. Anticipation of an anxiety-provoking stimulus causes people with Social Phobia to show highly elevated right-sided anterior cortical activation. Functional deficits in right-sided PFA-striatal circuitry is related to Attention-Deficit/Hyperactivity Disorder (ADHD) symptomatology, and persistent symptoms of ADHD prevent normal cortisol release in response to stressful conditions. Maturational deficits in PFC may predispose individuals to Schizophrenia, which is characterized by cerebral asymmetry and severe blunting of HPA activity and cortisol release.

Individual and Social Processes in Emotion Regulation and Psychopathology

A number of personality and interpersonal processes contribute to emotion regulation. Some of these have received too little attention in basic research.

Emotion System Functioning

Founders of the disciplines of biology and psychology called attention to the dynamic relations among emotions and the power of one emotion to influence another (Darwin, 1872/1998; James, 1890/1965). Tomkins (1962, 1963) greatly extended and elaborated this principle and described emotion-emotion dynamics in psychopathology, for example, the shame-fear bind in paranoid Schizophrenia and the sad-mad pattern in prolonged distress or depression (Tomkins, 1963). More recent empirical studies have confirmed the foresight of these early thinkers and demonstrated, for example, that anger is about as prominent as sadness in depressed children (Blumberg & Izard, 1986) and adults (Marshall & Izard, 1972). One can surmise that in these potentially pathological patterns of emotions, one emotion attenuates or amplifies the effects of another, as when shame leads to anger and violence (Baumeister et al.,

1996; H. Lewis, 1971; Tangney, Wagner, Barlow, Marshall, & Gramzow, 1996). One could interpret cognitive and cognitive-behavioral therapy techniques, such as distraction and restructuring, as devices to elicit a new emotion to attenuate or eliminate an undesirable one.

Emotion-Cognition Relations in Emotion Regulation and Psychopathology

Since the early phase of the emotion revolution in psychological science, researchers have acknowledged the significance of emotion-cognition relations for adaptation (Cicchetti & Schneider-Rosen, 1984; Izard, 1978; Izard, Kagan, & Zajonc, 1984). Imagery, distraction, and cognitive restructuring or reinterpretation for managing attentional and cognitive processes are widely used as emotion regulation techniques in everyday life as well as in various approaches to psychotherapy (e.g., Beck, 1976). As shown in later sections of this chapter, missing, ineffective, or dysfunctional connections between emotion and cognition characterize certain psychological disorders.

Research attests to the importance of the early development of emotional understanding and the significance of emotion knowledge for emotion regulation and coping strategies (Cutting & Dunn, 1999; Izard et al., 2001; see Denham, 1998, and Harris, 1999, for reviews). Emotion perception and emotion labeling, which form the foundation for emotion knowledge (Izard, 2001) and the construct of emotional intelligence (Salovey & Mayer, 1990), are subject to environmental influences that create perceptual-cognitive biases in information processing (Barth & Bastiani, 1997; cf. Crick & Dodge, 1994). These biases can put the individual at risk for aggressive behavior and become symptoms of other forms of psychopathology (Fine, Trentacosta, Izard, Mostow, & Campbell, 2004; Schultz et al., 2000).

Interpersonal Relations, Emotion Regulation, and Psychopathology

Relations between emotions and the prototypical social relationship, infant-mother attachment, run deep and strong (Ainsworth et al., 1978; Bowlby, 1980; Izard, Haynes, Chisholm, & Baak, 1991). Some theorists have explicitly recognized interpersonal relationships as a highly significant contributor to emotion regulation (Izard & Kobak, 1991). Disruptions of the attachment relationship elicit strong expressions of the discrete emotions of anger (protest) and sadness (despair, call for help) in 13-month-old infants (Shiller, Izard, & Hembree, 1986). Disruptions in attachment appear to place children at risk for psychopathology (Kobak, Little, Race, & Acosta, 2001). Strong

emotion responses to attachment disruptions, separation, or loss of a loved one continue throughout the life span (Izard & Ackerman, 1997).

Causal Processes in Psychopathology

The high degree of specialization that characterizes today's science makes it difficult to gain perspective on causal processes. Today's highly specialized scientists may tend to see the roots of a problem as lying solely or primarily in their domain of expertise. We often make claims such as this one: The data suggest that cortisol activity may add to our understanding of behavioral development (Smider et al., 2002). An approach conscious of the interdependence of highly interactive neurobiological and psychological systems might word the claim more like this: "Within the context of the current set of predictors, variable X accounts for unique variance in outcome Y."

Selective perception of variables in a particular domain as dominant or unique predictors may serve to advance knowledge, particularly within specialties, but it may fail to keep the complexity of the broad picture clearly in mind. Our review in this chapter undoubtedly reflects our selective perception of the significance of the individual and social functions of emotions, especially in relation to cognition and behavioral coping strategies, in normal and abnormal development. Nevertheless, we consider the contributions from research on neurobiological systems and social relationships as they relate to discrete emotions, the emotions system, and the development of psychopathology. The extent to which researchers have considered multilevel causal processes in the development of a particular type of psychopathology varies across psychological disorders and the specific diagnostic categories.

EMOTIONS AND THE DEVELOPMENT OF PSYCHOPATHOLOGY IN INFANCY AND EARLY CHILDHOOD

In this section, we discuss the role of emotions in the development of psychopathology in very young children. Perhaps at no other stage of life are the intrapersonal and social functions of emotions so inextricably linked as in infancy and early childhood. In this early stage of development, the primary context in which emotional development takes place is the relationship between the child and the primary caregiver on which its life depends. Within this relationship, emotion patterns and affective-cognitive structures

begin to self-organize, the brain's emotion centers develop and are shaped by the affective displays of the caregiver and caregiving experiences, and the ability to regulate the expressive components of emotion experience emerges. However, the infant is not merely an empty vessel to be filled with whatever affective experience the caregiver provides, but is an active agent, bringing to the table tendencies and thresholds for emotion perception, expression, and regulation. These evolutionarily and genetically determined qualities in the infant exert significant influence on the caregiver and result in reciprocal cycles of emotion patterns for both participants in the relationship (e.g., Gianino & Tronick, 1992; Tronick & Weinberg, 1997). The consequences of these early patterns of dyadic interaction between caregiver and child reverberate throughout the child's life, sowing the seeds for both normal and abnormal developmental trajectories (M. Lewis, Feiring, & Rosenthal, 2000).

Child maltreatment is perhaps the most damaging circumstance in caregiver-child relationships and has the potential to derail normal development of intersystem connections between the cognitive and emotions systems, perception of emotions in the self and others, and neurobiological mechanisms that regulate emotion experience and expression (Cicchetti & Lynch, 1995). However, maltreatment often co-occurs with several other factors that can also hamper emotional development, including maternal psychopathology, poverty, intrauterine drug exposure, and an environment that may expose the child to violence and multiple caregiver changes (Morrison, Frank, Holland, & Kates, 1999). This cluster of factors can coalesce to create a pressure cooker of stress in which the infant emotion systems are developing and self-organizing, and it is during the first 3 years of life when maltreatment and its cofactors can have the most destructive effects (Mrazek, 1993).

As we have become more aware of the importance of early emotional development for later adaptive functioning and the vulnerability of infants and toddlers to adverse environments, so also have we become more attentive to patterns of maladaptive emotion expression and regulation in the first few years of life. However, the field of detection and diagnosis of early childhood psychopathology is itself still in its infancy. Researchers and practitioners have developed and are in the process of refining and determining empirical support for a system of diagnostic classification for mental disorders in children up to 3 years old (DC: 0 to 3, *Diagnostic Classification of Mental Health and Developmental Disorders of Infancy and Early Childhood*, Zero to Three, 1994; Cesari et al., 2003; Emde & Wise, 2003; Guédeney et al.,

2003; Stafford, Zeanah, & Scheeringa, 2003). The DC: 0 to 3 system describes some of the early symptoms of derailed emotional development in an attempt to go beyond simply downward-scaling adult disorders described in the *Diagnostic and Statistical Manual of Mental Disorders IV*. This system focuses on developmentally salient aspects of affective experience, regulation, and behaviors and emphasizes the context and role of the caregiver-child relationship in the emergence of early problems. We refer to this classification system in our discussion of the role of emotions in the development of early disorders.

Developmental Functions of Emotions in Infancy and the Caregiver-Child Relationship

The infant emerges into the world prepared to detect and respond to emotions from adults who are essential for its survival. Newborns show a preference for the human face above other visual stimuli and exhibit the ability to detect and respond to facial signals and engage in nonverbal communication. They stick out their tongue and open their mouth in response to adult expressions (Meltzoff & Moore, 1983). These behaviors suggest that infants have a predisposition to attend and respond to facial expressions in the primary caregiver. During this first stage of life, emotions provide an essential survival function, as the infant engages adults with expressions of joy, enlists the aid of caregivers with expressions of sadness or fear, and explores its environment when motivated by the emotion of interest. When these evolutionarily influenced emotions do not achieve the intended (or adaptive) caregiver response over time, as in the case of an infant whose mother is depressed or for a child whose caregiver is abusive or neglectful, these modular emotion systems can become dysregulated, producing rippling changes in the child's threshold for and organization of emotion experience and expression, neurobiological regulation of emotion, and perception of emotions in others and self.

Beyond basic survival functions, emotions in both the infant and the caregiver play an essential role in the formation of an attachment bond during the 1st year of life, the very context in which children first experience emotional reciprocity and regulation. Negative emotion expression in both mothers and infants are significant predictors of attachment security (Izard, Haynes, et al., 1991). Maternal depression is also predictive of insecure attachment in infants (Martins & Gaffan, 2000). S. B. Campbell et al. (2004) found that maternal depression interacted with maternal sensitivity to predict preschoolers' attachment security, such that depressed moth-

ers with low sensitivity were more likely to have insecurely attached preschoolers than were depressed mothers who were highly sensitive to their children.

Attachment security is predictive of consistency in use of emotion regulation strategies, emotion dysregulation, and both internalizing and externalizing behaviors in later childhood (M. L. Diener, Mangelsdorf, McHale, & Frosch, 2002; Gilliom, Shaw, Beck, Schonberg, & Lukon, 2002; Vondra, Shaw, Swearingen, Cohen, & Owens, 2001). Disorganized attachment, which may be due in part to interactions that provoke fear in the infant as a result of the caregiver's behaviors and therefore confusion as the infant seeks to regulate its experience of fear by seeking proximity to the adult that triggered the emotion, has been linked with both aggressive behavior in childhood and development of psychopathology in later life (van Ijzendoorn, Schuengel, & Bakermans-Kranenburg, 1999). Some have suggested that these resultant aggressive behaviors may themselves be maladaptive attempts at emotion regulation (van der Kolk & Fisler, 1994). From these findings it is clear that normal emotional development in early childhood is not only determined by the inborn characteristics and developmentally salient emotions of the child but is also greatly influenced by the emotional behaviors, expressions, and perceptions of the caregiver.

Early Development of Intersystem Connections

As the emotions systems develop and self-organize, connections form between cognitions and emotions and between different discrete emotions. These connections are initiated and solidified as a result of early experiences such as affect perception of emotions in others and emotional responses to situations. Developmental theory suggests that internalized early representations of caregivers provide fundamental organizing information for children's emotion responses to others and point to the role of maladaptive intersystem connections in the development of psychopathology early in life. Children who have been maltreated by their caregivers form negative relational schemas that mediate the relation between maltreatment and rejection in late childhood peer relationships (Shields, Ryan, & Cicchetti, 2001). In these situations in which the caregiver may exhibit angry, abusive behaviors, affective-cognitive structures may form that link representations of interpersonal relationships with the emotions of anger, fear, or sadness. Emotion patterns may also form, yoking fear at the caregivers' behavior to anger and subsequent aggressive behaviors.

Maladaptive intersystem connections may result in later emotion perception errors. For example, physically abused children tend to perceive anger when it is not present (Pollak, Cicchetti, Hornung, & Reed, 2000), which has been found to predict aggression (Fine et al., 2004). Neglected children tend to have difficulty discriminating and identifying emotion expressions (Fries & Pollak, 2004; Pollak et al., 2000). Although connections between certain actions or expressions and the emotion systems may result in more rapid evaluation and perception of emotion and promote mobilization of a response that promotes self-preservation (M. M. Bradley & Lang, 1999; Pollak & Sinha, 2002), outside of the maltreatment context they may place the child at a disadvantage. These connections may serve an essential survival function for a vulnerable child in a threatening environment, but automatic triggering of negative emotions in peer relationships may result in inappropriate social behaviors.

Emotions systems may also interconnect with memories of certain events, and in the case of trauma can result in the emergence of disproportionate emotion responses to certain environments or other stimuli. Upon the introduction of a traumatic stimulus, the child may experience overwhelming fear or terror, while the brain reacts through a complex and cascading series of intracellular reactions that stimulate the HPA system and release neurohormones that prepare the body to respond to the threat (Kaufman & Charney, 2001). However, these immediate biological and experiential components of emotion responses are not the terminal consequence of trauma. Instead, they may represent the initial events in a series of self-organizing intersystem connections that play a role in the development and maintenance of longer-term symptoms of Traumatic Stress Disorder (Zero to Three, 1994).

Once the traumatic event or circumstances have ended and the child is in a safe environment, there is a possibility that the trauma has had such an intense impact on the emotions systems that it is prominently imprinted in the child's catalogue of experience. Therefore, one of the symptoms that typifies Traumatic Stress Disorder is some reexperiencing of the traumatic incident(s) through compulsive and repetitive play, distress at reminders of the trauma, or dissociative behaviors (see Streeck-Fischer & van der Kolk, 2000, for a review). These symptoms clearly involve memories of the traumatic and stressful circumstances linked with intense and overwhelming emotions, including terror and despair. An example of reexperience of a trauma is a toddler who was exposed to conditions of chronic deprivation and, after having lived in a safe and nurturing foster

home for several months, continued to gorge food to the point of choking and compulsively grabbed food from others' plates during meals. Although the toddler's foster care environment presented no real threat, she continued to experience the fear and distress of impending starvation at each meal. In this example, the situation involving food triggers a cognitive-affective-behavior structure in which the memory of deprivation has formed a link with the fear emotion system. Once triggered, the emotion of fear leads to a behavior (i.e., gorging) previously associated with survival but that is inappropriate to the current situation.

The emotions systems also play a role in several aspects of memory function, such as the content, accuracy, intensity, and accessibility of memories (Pollak, Cicchetti, & Klorman, 1998; Post, Leverich, Xing, & Weiss, 2001). Post and colleagues likened the intrusive memories or reexperiencing a traumatic event to "affective seizures," analogous to the motor seizures that typify the neurological disorder of epilepsy. Similar to the kindling model of epilepsy, repeated experiencing of the traumatic memory may eventually lead to spontaneous, untriggered reexperiencing and intense emotion which, if left untreated, has an ever-increasing negative impact on individual functioning. In the aftermath of chronic maltreatment or deprivation, the developing brain may be more vulnerable to formation of abnormal emotion-memory connections and low thresholds for activation of both the reexperience of the trauma and accompanying flooding of negative emotions such as fear or sadness. These affective-cognitive structures and the thresholds for their activation may solidify and crystallize in the absence of early intervention, resulting in increased risk for the development of affective and behavioral disorders, as well as hampered formation of additional attachment relationships throughout childhood, adolescence, and adulthood (Post et al., 2001).

Emotion Expression in Caregiver-Infant Relationships

Expressions of emotions from both infants and caregivers provide essential communication signals that influence responding and impact the infant's emotional development (Izard et al., 1995). Thus, emotion expressions from both partners play a key role in the emergence and experience of psychopathology in infancy and early childhood. In typical emotional development, infants rely on expressions of their caregivers to provide information important to survival. Infants quickly learn to reference their caregivers' expressions and vocal tone when introduced to novel stim-

uli (Moses, Baldwin, Rosicky, & Tidball, 2001) and match caregivers' expressions with their own (Termine & Izard, 1988). When caregivers are experiencing depression and exhibiting frequent expressions of sadness and constriction of affective expression in general, infants also show early signs of derailed emotional development, exhibiting angry and sad facial expressions earlier and more frequently than infants of nondepressed mothers (Jones, Field, Fox, Lundy, & Davalos, 1997).

Although negative emotion expression from the caregiver does not necessarily represent a maladaptive pattern of interaction (see Halberstadt & Eaton, 2002, for a review), hostility expressed about the child in conversation has been associated with increased risk for verbal abuse (Calam, Bolton, Barrowclough, & Roberts, 2002). Economically disadvantaged children of mothers who show high levels of negative emotion expression were less accurate in their understanding of anger cues and anger-related terms (Raver & Spagnola, 2002). Parental expressions of anger during direct interactions with their young children predict later behavioral difficulties (Denham et al., 2000). In some cases, parental anger displays or expressions of fear due to past trauma engender fear and conflict that disorganizes the attachment bond (van Ijzendoorn et al., 1999). Thus, frequent and intense caregiver expression of negative emotions impact very young children's ability to perceive emotions in others and regulate their own emotion experiences.

Frequency of negative emotion expressions in infancy is also predictive of early problems and difficult temperament in toddlerhood (Abe & Izard, 1999b), which may promote a reciprocal cycle of negative emotions and punitive responses from the caregiver that continues throughout childhood (Eisenberg et al., 1999). However, expressions of negative emotions themselves are not inherently maladaptive. Infants use negative emotion expression to signal the need for assistance and comfort from a caregiver, and the negative emotion of anger provides motivation to remove a frustrating barrier to mastery of tasks or acquisition of a desired object (Abe & Izard, 1999a). Emotion expression becomes maladaptive when it interferes with normal developmental functioning. In extreme cases, young children's experience of sadness or fear becomes so overwhelming that it constitutes a primary affective disorder (Zero to Three, 1994). In adults, disorders such as depression and anxiety are typified not only by displays of negative emotion but also by cognitions such as thoughts of hopelessness or of undesirable events that might take place (American Psychiatric Association, 1994). In very young children, these disorders have been primarily characterized either by

intense, prolonged negative emotion expression or very constricted expression of emotions and are often associated with, but not specific to, a primary caregiving relationship (Zero to Three, 1994).

Regulation of Emotion Systems in Infancy and Early Childhood

One of the most important developmental tasks in early childhood is the formation of strategies for successful regulation of negative emotions. Children who become derailed in their development of adaptive modulation of emotion may become so severely dysregulated that they are unable to pursue developmentally salient activities. As described by the DC: 0 to 3 system, the diagnosis of a primary regulatory disorder suggests an overarching deficit in the regulatory systems, including emotion regulation, that results in unusual patterns of behavior characterized by either undercontrolled or overcontrolled expression of emotion as well as other behavioral responses to the environment (Zero to Three, 1994). Although direct empirical links have not yet been established, it may be that children who have been maltreated are more likely to experience primary regulatory disorders, as maltreated preschoolers are much more likely to exhibit either undercontrolled or overcontrolled dysregulated emotion patterns than are non-maltreated preschoolers (Maughan & Cicchetti, 2002).

In normal development, caregivers provide a close relationship with the infant that affects the actual formation of brain structures that influence social responding, feelings of well-being, and emotion regulation (see Kraemer, 1992, for a review). Synchrony in maternal-infant displays of affect, a situation in which the mother modulates her own affect to "follow the child's lead" with respect to facial expressions and behaviors, is predictive of self-regulation in toddlerhood, particularly for infants with difficult temperament (Feldman, Greenbaum, & Yirmiya, 1999). Consistent maternal emotion responsiveness in early childhood, characterized by frequent displays of positive emotions, influences the development of adaptive social interactions and emotion regulation in young children (Landry, Smith, Swank, Assel, & Vellet, 2001). This type of consistent responsiveness requires adaptive emotion regulation on the part of the caregiver that allows her to modulate her own inner emotion experience depending on the affective needs of the child. When the caregiver is experiencing severe dysregulation in her own emotion systems, whether because of depression or some other psychopathology, the infant is placed at risk for abnormal or nonoptimal

emotional development and insecure attachment (Ashman, Dawson, Panagiotides, Yamada, & Wilkinson, 2002; Hipwell, Goossens, Melhuish, & Kumar, 2000). For example, prolonged stress, such as that experienced by the child of a depressed mother, has long-term implications for hormone levels and electrical activity in the brain, which are in turn related to the development of affective disorders (Ashman et al., 2002; Dawson et al., 1999). The impact of emotional stress has been detected as early as infancy, when patterns of increased right frontal brain activity have been identified in children as young as 1 month of age who have depressed mothers (Jones et al., 1997).

Child maltreatment also has negative implications for the development of adequate emotion regulation. Children who have experienced maltreatment show abnormal neurobiological patterns, such as elevations in morning salivary cortisol levels, which have also been linked with children's processing and regulation of emotion (Cicchetti & Rogosch, 2001a, 2001b). Maltreatment also directly relates to deficits in children's ability to regulate their emotional experiences (Maughan & Cicchetti, 2002), and emotional dysregulation mediates the maltreatment-externalizing relation (Shields & Cicchetti, 2001). However, some research suggests that parental socialization of emotion expression further mediates the relation between maltreatment and child emotion dysregulation, such that maltreated children who have fewer expectations of support for their displays of emotion have more difficulty generating adaptive ways of coping with and regulating anger (Shipman & Zeman, 2001).

Maltreating caregivers' response to their children's emotion displays is clearly an important mechanism through which children learn to internally regulate their affective experience and points to potential deficits in the caregiver's own emotion-processing abilities that predict regulation difficulties in the child. Caregivers who abuse or neglect their young children show less emotion perspective-taking and less understanding of their children's emotion displays (Shipman & Zeman, 2001). Although results are mixed, there is some evidence that maltreating caregivers make more errors in their perception of facial expressions of emotion and may show a tendency to perceive negative emotions and hostile intent in the affective signals of their children (Balge & Milner, 2000; Milner, 1993; cf. Camras et al., 1988).

When caregivers misperceive their children's emotion displays or are unable to cope with negative displays of emotion from children, they may respond punitively in these situations rather than supporting or coaching the child to successfully and adaptively regulate intense nega-

tive emotion. Some parents may have difficulty regulating their own responses to child negative emotion and experience increased distress in these situations. Parental distress in response to children's negative emotion adversely affects their ability to help externally regulate child emotion in ways that help lower the intensity of the child's experience and outward display and is negatively related to children's ability to understand emotions (Fabes, Leonard, Kupanoff, & Martin, 2001). Punitive responses to children's negative emotion displays are negatively related to children's ability to regulate intense negative emotions (Eisenberg et al., 1999). Reciprocal cycles of dysregulation between parents and children suggest a model of intergenerational transmission of nonoptimal emotion experiences that derail emotional development and lead to the emergence of psychopathology.

EMOTIONS AND DEPRESSION

Depression is in many respects a prototypical disturbance of emotion. Mood disturbance is the defining feature of unipolar and bipolar depressive disorders. Considerable research has examined the role of emotion in depressive disorders, including attention to the subjective emotional experience of individuals suffering from depression, emotion regulation, emotion recognition and mood-congruent memory, emotion expression, and the neurophysiological substrates of emotional contributions to depression. After an overview of the neurobiology of depression, this section focuses on dimensional models of emotion and depression and then on the role of discrete emotions in depression.

Overview of Neurobiology of Emotions in Depression

Studies at the cognitive and behavioral levels indicate that the affective symptomatology of depression includes loss of interest and enjoyment, increased sadness, shame, and guilt, and the tendency for prolonged sadness to elicit inner-directed anger (Blumberg & Izard, 1985; Marshall & Izard, 1972; also see H. Lewis, 1971; Tomkins, 1963). Thresholds for the activation of these emotion systems undoubtedly have determinants in both biogenetic and environmental processes. Infants' capacities to perceive the world as affectionate and friendly or indifferent and hostile emerge from brain systems that subserve the positive emotions of interest and joy and the negative emotions of sadness, shame, guilt, and anger (cf. Panksepp, 2001). Neuroscientists have begun to map the neural circuitry of these emotions and trace their development. They have long rec-

ognized that the development of such brain systems depends in large part on environment and early experience (Greenough et al., 1987). Scientists have not yet determined whether biogenetic substrates or environmental factors have primacy in causal processes (Davidson et al., 2002). The evidence does suggest that the interplay of biological and social factors is critical in the development of depression.

Drawing largely on the work of Damasio (1994), Davidson and his colleagues (Davidson, 2000; Davidson et al., 2002), and A. L. Miller et al. (2002), we identify the several brain systems or neural circuitries involved in the activation and regulation of the emotions in depression and indicate how they may contribute to the disorder. Researchers have identified relevant systems in the prefrontal cortices (PFC), anterior cingulate cortex (ACC), hippocampus, and amygdala.

The Prefrontal Cortex

As noted earlier, the PFC plays a highly significant role in emotion, higher-order cognition, and emotion-cognition relations (Bechara et al., 1997; Damasio, 1994). The role of the PFC in depression may be explained by the fact that it houses the representational processes involved in goals and goal-directed coping strategies (E. K. Miller & Cohen, 2001). Lesions in the ventromedial PFC reduce or eliminate the emotion arousal that normally guides decision-making processes in risky situations (Bechara et al., 1997; Damasio, 1994). Resulting maladaptive choices and subsequent losses and problems can contribute to sadness and the patterns of emotions in depression. Researchers have also linked vulnerability to negative mood states and depression to left hemisphere PFC hypoactivation and right hemisphere PFC hyperactivation (Davidson et al., 2002). In EEG studies, several investigators have reported the neurological symptoms of reduced left relative to right PFC activation. Yet, this pattern of apparently asymmetrical functioning in the left and right brain hemispheres does not always appear in depression (Davidson et al., 2002), and it may vary with the sex and psychiatric history of the individual (A. L. Miller et al., 2002). Some evidence suggests that variability in PFC activation may itself constitute a symptom of depression (Debener et al., 2000).

Anterior Cingulate Cortex

The ACC is a crucial region of the brain for the interaction of emotion, attention, and working memory (Damasio, 1994). Research indicates that the ACC has functionally distinct regions for emotion processes (rostral and ventral areas) and cognitive processes (dorsal areas). Consistent

with the assumption that the ACC plays a critical role in the neurophysiological processes in emotion regulation, its emotion area has extensive connections to the PFC, amygdala, hypothalamus, and brainstem (Devinsky, Morrell, & Vogt, 1995). Damage to the ACC (and possibly adjoining PFC areas) creates a condition of “suspended animation” characterized by absence of expressive behavior in face and body, as well as inability to reason and an apparent lack of emotion feelings (Damasio, 1994, p. 71).

The symptoms of neurological patients with damage to the ACC may bear some similarity to those found in extreme forms of depression, where a seemingly total lack of the positive emotions of interest and enjoyment leads to drastically maladaptive disengagement with the social and physical environment (Marshall & Izard, 1972). Several investigators have indeed observed decreased ACC activation in Major Depression. The decreased activation appears in the dorsal region, which may relate to effortful control (see Davidson et al., 2002, for a review). Researchers have related developmental increases in effortful control to maturation of the ACC, as well as the PFC and its associated executive functions. They have identified effortful control as a temperament factor that plays a critical role in the development of emotion regulation, self-control, and adaptive behavior (Posner & Rothbart, 2000). Although a number of behavioral neuroscientists have speculated about cross-talk among these brain areas, understanding the functional relations between the emotion and cognitive areas of the ACC, between them and the PFC, and the implications of these interactions for adaptive behavior and psychopathological conditions such as depression remains a challenge for future research.

The Hippocampus

The hippocampus participates in important aspects of cognition, and its integrity is critical to the creation of memories of new facts (Damasio, 1994). It subserves contextual, spatial, declarative, and episodic learning and memory (see Davidson et al., 2002, for a review). Apparently due to their inability to form and retain memories of provocative events, neurological patients with damage to the hippocampus often experience emotions without conscious awareness of the cause or activating event (Damasio, 1999). An inability to remember the facts or circumstances that cause an emotion might make its regulation more difficult and its duration longer, conditions that characterize Major Depression. Although hippocampal dysfunction may relate to depression and other forms of psychopathology, hippocampal activity occurs with positive as well as negative emotion arousal (see Davidson et al., 2002, for a review). Its

role in emotion and depression may stem from its unequivocal effects on learning and memory, both of which are prominent mediators of emotion activation. Individuals suffering either depression or anxiety disorders show a deficiency in their ability to experience and express emotion appropriate to the context, a context regulation problem that results in context-inappropriate expressions of feelings (Davidson, Jackson, & Kalin, 2000).

Major Depression is associated with decreased hippocampal volume as well as hippocampal dysfunction that may result in decreased inhibitory regulation of the HPA system. These conditions, however, also characterize other forms of psychopathology (e.g., Posttraumatic Stress Disorder and Borderline Personality Disorder). Moreover, these findings come from correlational studies and do not identify cause-effect relations (Davidson et al., 2002). Some evidence suggests that in females, the decrease in hippocampal volume is associated with lifetime duration of depression and is thus a symptom rather than a cause (Sheline, 2000). In any case, substantial evidence supports the correlation.

The Amygdala

The literature reveals three findings relating the functioning of the amygdala to depression (Davidson et al., 2002). As in the case of the hippocampus, the data show correlations, not cause, and some inconsistencies across studies. The first of these findings, more often supported than not, shows a relation between increased volume in the amygdala, particularly left amygdalar volume, and depression. Second, some investigators have found increased blood flow or glucose metabolism in the amygdala of depressed patients. Third, several studies have shown a positive correlation between trait-like negative emotionality and Manic Depressive Disorder. Consistent with this finding is the observation that relief from depression mediated by antidepressant drugs is accompanied by a decrease in amygdalar activation.

Status of the Neurobiology of Depression

Neurobiological research has revealed a number of promising leads regarding the causes and effects of depression. Current evidence reveals that some brain and neural systems (e.g., the prefrontal and anterior cingulate cortices, hippocampus, and amygdala) are more involved in depression than others. The findings are consistent with the conceptual framework of this chapter and underscore the necessity of a multifaceted, multilevel, cross-disciplinary approach to the study of depression, as well as other forms of psychopathology.

Dimensional Models of Emotion in Depression

Several different models of emotion and motivation have been productively applied to depression. We focus on four: (1) motivational models concentrating on behavior activation and behavioral inhibition; (2) approach and withdrawal models of emotion; (3) the two-dimensional, positive and negative affect models of emotion, which have been elaborated into the tripartite model of depression and anxiety, and (4) three-dimensional models of emotion space that include a dimension of dominance or perceived control. As will be seen, there is considerable overlap among these models, offering opportunities for integration.

Motivational Systems Model: Behavioral Activation and Inhibition

Depressive disorders offered a prototype for the development of biological models of psychopathology focusing on motivational systems (Depue & Iacono, 1989; Fowles, 1994; Gray & McNaughton, 1996). These motivational models have since been generalized to other major forms of psychopathology (Beauchaine, 2001; Beauchaine, Katkin, Strassberg, & Snarr, 2001; Depue, 1996; Fowles, 1994; Johnson & Roberts, 1995; Quay, 1993, 1997).

Gray (Gray & McNaughton, 1996) has developed an influential model of biological motivational systems. Rooted in neurophysiology, Gray's model hypothesizes that three distinct motivational systems impel much of our behavior. Although these systems served adaptive functions over the course of evolutionary history, it is possible for these systems to lead to maladaptive expressions, either due to extreme individual differences or because of the transaction between the organism and specific environmental demands. Thus, these systems undergird both normal functioning and pathological processes.

The three systems in Gray's model include the Behavioral Activation System (BAS), Behavioral Inhibition System (BIS), and the Fight or Flight System (FFS). The FFS has received much less attention than the other motivational systems; most discussions of Gray's model concentrate on the BAS and BIS exclusively (Matthews & Gilliland, 1999). However, it is worth bearing in mind that Gray posited a third dimension. The FFS may prove helpful in reconciling Gray's model with other theories and observations described later (e.g., White & Depue, 1999).

The BAS motivates approach behaviors, including social engagement and positive valence emotion experiences such as happiness. The BAS may also be associated with subjective feelings of confidence, pleasure, drive to obtain a goal, and anger. BAS also appears linked to reward

dominance and sensation seeking (Zuckerman, Joireman, Kraft, & Kuhlman, 1999), constructs that emphasize an individual's willingness to seek out hedonic stimulation. At a neurophysiological level, the BAS involves primarily dopaminergic pathways (Carver & White, 1994; Gray & McNaughton, 1996).

The BIS motivates withdrawal behaviors, including social avoidance and harm avoidance. In neurophysiological terms, the BIS appears to involve serotonergic or norepinephrine pathways. The BIS is oriented toward cues of harm or punishment, and it inhibits ongoing behavior in the presence of novel stimuli or signals of nonreward (extinction) or punishment. The BIS and BAS are thought to be distinct but antagonistic systems, analogous to the brake and gas pedals in a car (Mash & Wolfe, 1999).

Investigations examining the relationship of BAS and BIS to emotion experiences or personality traits have mapped out a logical set of associations. High levels of BAS are associated with higher trait extraversion, sensation seeking, and agreeableness. High BAS also appears to be associated with increased self-report of positive emotions such as happiness, joviality, and excitement. Conversely, BIS appears most strongly associated with trait neuroticism and negative affect. BIS shows strong correlations with measures of anxiety and shyness (Matthews & Gilliland, 1999).

Depression Involving High Behavioral Inhibition System, Low Behavioral Activation System. In Gray's model, unipolar depression is a condition involving a combination of pathological elevations of BIS and low levels of BAS. At the symptomatic level, the high activation of the BIS would be associated with increased negative affect, increased shyness, and increased tension and somatic complaints, such as psychomotor agitation. The markedly low level of BAS would be associated with a sense of anhedonia (i.e., "loss of interest in activities that used to be pleasurable"; American Psychiatric Association, 2001, p. 349), and a lack of motivation to engage in social interaction or other reward-oriented activity. The antithesis of depression, in BIS/BAS terms, would be Conduct Disorder: Various theoreticians have formulated Conduct Disorder as representing the combination of low BIS (resulting in disinhibition and decreased salience of punishment) with high BAS (leading to high reward dominance and the pursuit of short-term goals without concern for the long-term consequences; Fowles, 1994; Hare, 1999; Quay, 1993).

Depue has developed a very similar model of depression, although he uses slightly different terms, referring to the approach/positive emotion system as the Behavioral Fa-

cilitation System (BFS) instead of BAS (Depue & Iacono, 1989). Depue more recently has been focusing on three personality "superfactors" that include emotional and neurobehavioral substrates: positive affectivity, which primarily involves dopaminergic pathways (Depue & Collins, 1999; Depue & Lenzenweger, 2001; Depue, Luciana, Arbisi, Collins, & Leon, 1994); constraint, principally linked to serotonergic (5HT) functioning; and negative emotionality, also principally linked to serotonergic (5HT) functioning (Depue, 1996). Like Gray, Depue conceptualizes unipolar depression as involving hypoactivation of the BFS/BAS and hyperactivation of the BIS or negative emotionality system (Depue & Iacono, 1989; Depue & Lenzenweger, 2001).

Mania as Behavioral Activation System Dysregulation. Bipolar Disorder, or manic depression, is characterized by the occurrence of depressive as well as hypomanic or manic episodes (American Psychiatric Association, 2001). The emotional and behavioral presentation of a depressive episode in Bipolar Disorder is largely indistinguishable from a unipolar depressive episode. In both cases, the depressive episode is likely to involve high levels of negative affect (i.e., high BIS) as well as low levels of behavioral activation or facilitation.

Hypomanic and manic episodes are defined by the same symptoms in the current psychiatric classification systems. Hypomania involves either less severe symptom expression or shorter duration. Both hypomania and mania can involve elated or expansive mood, irritability, grandiosity or inflated self-esteem, decreased need for sleep, pressured speech, racing thoughts or flight of ideas, distractibility, increased goal-directed activity (socially, academically, or sexually), or excessive involvement in pleasurable activities that have a high potential for painful consequences. With the exception of irritability, these symptoms map fairly neatly onto a putative behavioral activation system (e.g., BAS/BFS). Irritability might appear to be an exception if it is conceptualized as involving putatively negative emotions. However, the discrete emotion of anger is distinct from other negative valence emotions in several important respects, discussed later. Also, the irritability in mania seems most likely to manifest when people or circumstances impinge on the manic individual's pursuit of goal-directed behaviors.

Thus, hypomania and mania can be conceptualized as manifestations of dysregulation in the BAS. There is mounting evidence consistent with this formulation. Self-report measures of depressive symptomatology are positively correlated with reports of BIS and negatively correlated with

BAS. High self-reported levels of BAS/BFS are also markers for physiological differences in cortisol levels, dopaminergic activity, and lifetime history or future risk for the development of Bipolar Disorder (Depue & Collins, 1999; Depue, Krauss, Spont, & Arbisi, 1989; Depue et al., 1994; Klein & Depue, 1984; Klein, Depue, & Slater, 1985, 1986; Klein, Lewinsohn, & Seeley, 1996; Lewinsohn, Seeley, Buckley, & Klein, 2002).

Current models of Bipolar Disorder focus on dysregulation of both the BIS and BAS (Depue & Iacono, 1989; Depue & Zald, 1993; Johnson & Roberts, 1995). Low levels of BAS would lead to anhedonic depressive features. Moderate levels of BAS characterize “euthymic” behavior, or functioning within the normal limits of individuals without Bipolar Disorder. High levels of BAS activation could create hypomania, which generally feels subjectively pleasant and often involves extreme productivity, perhaps artistically as well as in the pursuit of other activities (Jamison, 1993; Lozano & Johnson, 2001). Extreme elevations of BAS result in the incapacitating aspects of mania, including disinhibited and impulsive behaviors that often lead to law-breaking and arrest (Hirschfeld et al., 2000; Pliszka, Sherman, Barrow, & Irick, 2000) as well as the more disorganized and psychotic presentations leading to emergency psychiatric hospitalization. High levels of BIS appear more associated with trait neuroticism (Lozano & Johnson, 2001), the negative affect symptoms associated with a depressive episode (Depue & Iacono, 1989), and potentially with the high rate of anxious symptoms observed in conjunction with Bipolar Disorder (Kessler, 1994).

Because BIS and BAS are thought to be independent systems and not polar opposites, it should be possible to experience states that involve varying degrees of activation of both systems. Although it was originally thought that Bipolar Disorder typically involved distinct episodes of mania and depression, often separated by periods of relatively euthymic functioning, data increasingly suggest that manic and depressive episodes can occur independently or simultaneously. Mania and depression appear to involve distinct risk factors or triggers (Alloy, Abramson, & Francis, 1999; Johnson, Meyer, Winett, & Small, 2000; Johnson & Miller, 1997; Johnson & Roberts, 1995; Johnson et al., *in press*). Additionally, mania and depression respond to different pharmacological agents: Lithium and anticonvulsants such as divalproex appear to have more pronounced antimanic properties, whereas compounds such as lamictal and selective serotonin reuptake inhibitors appear to have antidepressive qualities (Calabrese et al., 2000; Findling, Feeny, Stansbrey, DelPorto-Bedoya, & Demeter, 2002; Keck & McElroy, 2003).

The clinical phenomenon of “mixed states” also supports the theory that depression and mania might involve two separate systems that could potentially be dysregulated at the same time. Mixed episodes are periods during which an individual simultaneously experiences symptoms of both mania and depression. These have been recognized clinically since Kraepelin’s initial formulation of the syndrome of manic depression. In the BIS/BAS framework, mixed states represent the unfortunate confluence of high levels of activation of both BIS and BAS. Mixed states are described as being subjectively terrible experiences, “black manias” that are intensely unpleasant (Jamison, 1993, 1995). Actuarial statistics bear out a higher association between mixed states and suicide attempts or arrests for violent behavior (Goodwin & Jamison, 1990; Pliszka et al., 2000).

The BIS/BAS framework generates an interesting prediction, which, to our knowledge, has yet to be tested. If mixed states represent high activation of both BIS and BAS, then the depressive symptoms expressed during a mixed state should not include those symptoms that would be associated with low BAS activation. Instead, mixed states should primarily reflect the depressive symptoms that would be linked to high BIS activation. Specifically, a BIS/BAS model of mixed states would predict that mixed episodes tend to involve higher levels of anxiety, excessive guilt, psychomotor agitation, and sleep disturbance (especially early morning awakening)—all features of high BIS activation. Conversely, mixed episodes should involve relatively few symptoms of anhedonia, lack of energy, or psychomotor retardation. These would all be features of low BAS activation and thus incompatible with the high BAS activation involved in a manic state. A corollary of the BIS/BAS model of Bipolar Disorder would be that individuals might experience times with high BIS activation but normal BAS activation. These periods should be characterized by the high BIS features of depression without the associated low BAS features. As we will see below, a high BIS combined with moderate BAS activation pattern is characteristic of anxiety disorders, and Generalized Anxiety Disorder (GAD) in particular. Thus, it is intriguing to consider the frequency with which Bipolar Disorder is reported to be comorbid with anxiety disorders (and GAD in particular; Kessler, 1994; Kessler, Rubinow, Holmes, Abelson, & Zhao, 1997). The finding that individuals dealing with Bipolar Disorder report high lifetime rates of GAD is consistent with the BIS/BAS model of independent motivational systems. Because relatives of bipolar probands are not at higher risk of GAD, and because GAD and Bipolar Disorder appear to have no shared genetic variance (Zuck-

erman, 1999), it seems plausible that what appears to be comorbid GAD in cases with Bipolar Disorder may actually be a high BIS and moderate BAS manifestation of the bipolar syndrome.

Neurophysiology and Approach/Withdrawal Systems

A largely independent line of scientific inquiry into the neurophysiological underpinnings of emotion has generated a two-dimensional model of approach versus withdrawal systems. The withdrawal system implicates negative emotions, such as shyness, fear, and sadness. The approach system clearly involves positive valence emotions such as happiness, enjoyment, and excitement; for a while, this system was equated with positive affect. However, anger appears to be an approach emotion, in spite of the fact that anger tends to be classified as a negative emotion in analyses of self-report (Tellegen, Watson, & Clark, 1999; Watson, 2000b; Watson & Tellegen, 1985; cf. Mehrabian, 1995b; Russell & Mehrabian, 1977; Youngstrom, Frazier, & Butt, 2003).

Withdrawal emotions appear associated with increased right hemispheric cortical activation, particularly of the right prefrontal cortical region. Conversely, approach emotions are associated with increased left hemispheric activation. Most individuals show greater resting activation of the left hemisphere than the right hemisphere. This pattern of activation suggests that people would generally report experiencing higher state levels of positive emotions than negative emotions. This hypothesis has been borne out by studies of subjective well-being (E. Diener & Diener, 1996) as well as state emotion (Watson, 2000b).

Individuals with depression show higher levels of right hemispheric activation as well as decreased left hemispheric activation, yielding a higher ratio of right:left activation than found in nondepressed individuals (Davidson, 1998, 2000; Tomarken & Keener, 1998). A more detailed discussion of the specific neurophysiological pathways occurs in a later section. For present purposes, it is important to note the congruence between the approach/withdrawal model and the BAS/BIS model. The withdrawal system of emotions corresponds closely with the characterization of the BIS: Both involve most of the negative valence emotions, both involve sensitivity to cues of threat, and both are associated with increased sympathetic autonomous activation. Similarly, the approach system of emotions aligns with the BAS system described by Gray and others. The inclusion of anger as an approach emotion, which initially seemed problematic when approach was being equated with positive emotionality, actually now appears consonant with observations of irritability and aggression in mania (Woz-

niak & Biederman, 1997; Wozniak et al., 1995). Along the same lines, some evidence suggests that anger can be associated with dopaminergic activation, consistent with a BAS or an approach model of emotion.

The approach/withdrawal model has illuminated understanding of the physiological underpinnings of emotion and also provided a physiological marker associated with depression. The right:left activation ratio appears to be both a state and trait marker for depression. Individuals who have recovered from a depressive episode tend to still have higher right:left ratios of cortical activation, suggesting a trait-like component that persists beyond the depressive episode. At present, it is unclear whether this ratio represents a preexisting diathesis for depression, or whether it is a reorganization of neural activation patterns that persists after the episode (a "scar" or kindling hypothesis; Post et al., 2001). However, depressive episodes entail even more marked right:left ratios of activation, and the activation asymmetry changes in response to interventions for depression as well as modalities such as meditation. For now, this body of work provides strong corroboration of the role of emotional systems in depression, possibly as a vulnerability factor, definitely as a state marker, and probably as a risk factor for relapse.

Positive Affect, Negative Affect, and Depression

The most prominent models of emotion structure in contemporary personality and social psychology focus on two major dimensions of emotion. These have been labeled *positive affect* and *negative affect* (Tellegen et al., 1999; Watson, Clark, & Harkness, 1994; Watson, Wiese, Vaidya, & Tellegen, 1999), *valence and arousal* (Lang, 1995; Russell, 1980), or *energy and tension* (Thayer, 1967, 2001). Statistically, these models are equivalent, resulting from rotations of a two-dimensional factor structure (Barrett & Russell, 1999). For the purposes of this review, we use the terms positive affect (PA) and negative affect (NA) for two reasons: In factor analyses of self-report data, the simplest structure usually corresponds to a PA-NA model, and the PA-NA terminology has been more commonly used in discussions of emotion and psychopathology (S. J. Bradley, 2000; Keltner & Kring, 1998; Kring & Bachorowski, 1999).

Two major conceptual advances pertaining to depression have developed through the application of the PA-NA model of emotion. One is the idea that trait NA, or an individual's predisposition to experience negative emotions with more frequency and intensity, increases the risk for the development of many kinds of psychopathology, including depression (S. J. Bradley, 2000; Watson & Clark, 1984; Zuckerman, 1999). High trait NA is likely to be the

confluence of genetic factors as well as learning history (Loehlin, 1992). Individual differences in emotion activation thresholds have important consequences in terms of interpersonal interaction (Keltner et al., 1995) and cognitive associations (Izard, 1991). Through the formation of “affective-cognitive structures,” emotions shape the building blocks of personality (Izard, 1993; Izard et al., 1993). Trait NA is strongly correlated with the personality factor of neuroticism or emotional instability, which also is correlated with most forms of psychopathology (Krueger, Caspi, Moffitt, Silva, & McGee, 1996), and with anxiety and mood disorders in particular (Krueger, 1999a). Conceptually, NA plays a central role in psychopathology. To the extent that pathology causes subjective distress, it by definition involves increases in state NA (Wakefield, 1997). High trait NA represents an individual difference in an adaptive emotional system that can, given the right environmental circumstances, support the development of what could be diagnosed as a psychiatric disorder.

The second major contribution of PA-NA models to the understanding of depression focuses on the differentiation of depression from anxiety. Depression and anxiety frequently co-occur. In diagnostic interviews, individuals meeting criteria for a mood disorder are very likely to also meet criteria for an anxiety disorder, and vice versa, especially when considering lifetime histories of functioning. Similarly, individuals reporting high scores on traditional measures of depressive symptoms are also likely to report high scores on instruments intended to measure anxiety (Clark & Watson, 1991). In fact, the correlation between measures of depression and anxiety often falls in the $r = .70$ to $.80$ range. This is high enough to raise concerns about whether these instruments truly are measuring distinct constructs (i.e., it challenges their discriminant validity; D. T. Campbell & Fiske, 1959). By the same token, there are questions about whether anxiety and depression truly represent distinct diagnostic entities. In addition to the challenge posed by the high rate of comorbidity, behavioral genetic studies have indicated that GAD and depression share both a common genetic component and a common factor of “individual-specific” or “unique environmental” experiences (Kendler et al., 1995). Based on this and other evidence, it has been argued that GAD may be a prodromal version of Major Depression (Mineka, Watson, & Clark, 1998).

Careful examination of the existing measures of anxiety and depression through the lens of the PA-NA emotion model generated the observation that most instruments were capturing NA in general, but without adequately measuring other emotion or symptom patterns that might

help differentiate anxiety and depression (Clark & Watson, 1991). This conceptual analysis led to the formulation of the tripartite model of depression and anxiety. According to this model, both anxiety and depression include high levels of NA as a core feature. Thus, measures that primarily tap NA will not be able to distinguish between the two syndromes. According to the tripartite model, what is unique to depression is a pronounced low level of PA. This pattern corresponds to the anhedonia and loss of interest in pleasurable activity and the lack of energy characterizing depressive states (Thayer, 1996). Anxiety disorders, on the other hand, do not involve diminutions of PA and may actually involve slight increases in some positive emotions such as interest-excitement (Izard & Youngstrom, 1996). Conversely, the tripartite model posits that anxiety disorders are marked by high levels of fear and physiological hyperarousal that are not implicated in depressive episodes (Watson, Clark, et al., 1995). Thus, the tripartite model makes the prediction that anxiety and depression should be distinguishable via profiles of emotion. The emotional pattern for depression would be low PA, high NA, and moderate fear and physiological hyperarousal (i.e., “within normal limits”). Anxiety disorders were posited to result in moderate PA, high NA, and high fear or physiological hyperarousal. By extension, the tripartite model also implies that truly comorbid anxiety and depression should involve the defining features of both anxiety and depression; in other words, comorbid anxiety and depression would include low PA and high fear/physiological hyperarousal at the same time, in addition to the shared component of elevated NA.

The tripartite model has been tested by multiple research groups using data from both multiple age groups and populations. These include college students (Burns & Eidelson, 1998; Joiner, 1996; Joiner et al., 1999; Watson, Clark, et al., 1995; Watson, Weber, et al., 1995), adults in the community (Krueger, 1999b; Watson, Clark, et al., 1995) or Air Force (Joiner et al., 1999), patient samples (Brown, Chorpita, & Barlow, 1998; Burns & Eidelson, 1998; Joiner et al., 1999; Krueger, 1999b; Watson, Clark, et al., 1995; Watson, Weber, et al., 1995), and school-age children in the community (Chorpita, 2002; Lonigan, Hooe, David, & Kistner, 1999), outpatient (Chorpita, Albano, & Barlow, 1998), and inpatient settings (Joiner, Catanzaro, & Laurent, 1996; Joiner & Lonigan, 2000). These studies have been remarkably consistent in terms of supporting the tripartite model’s formulation of depression as involving low PA and high NA. Findings have been more complicated with regard to anxiety and fear or physiological hyperarousal. Fear and physiological hyperarousal show the strongest relations to Panic Disorder (Brown et al.,

1998). GAD appears principally to correlate with high NA and not so much higher fear or physiological hyperarousal (Chorpita et al., 1998). This linkage of GAD with high NA actually is consistent with the high rates of psychiatric comorbidity and the shared genetic and environmental components between GAD and depression (which also implicates high levels of NA). Interestingly, simple phobias and Obsessive-Compulsive Disorder, both of which appear to have distinct genetic factors from GAD and Panic Disorder (Kendler et al., 1995), do not show strong associations with fear or physiological hyperarousal.

The tripartite model has clear implications for assessment. Tools that concentrate on the distinct emotional features of depression versus anxiety should do a better job of discriminating these conditions (e.g., the Mood and Anxiety Symptoms Questionnaire, which was developed specifically with the tripartite model in mind; Watson, Clark, et al., 1995). Such improvements in instrumentation would not only increase the accuracy of differential diagnosis, but they also will provide clearer definitions of phenotypes for the investigation of risk factors and treatment response. The tripartite model underscores the centrality of low positive affect, or anhedonia, as perhaps being the defining component of depression. If sadness and happiness are polar opposites, as suggested by some emotions researchers (Russell & Carroll, 1999), then the two core symptoms of depression in the *DSM* nosology, sadness and loss of interest in pleasurable activity, might actually be manifestations of the same emotional construct of low PA.

Three-Dimensional Models

Although most researchers currently ascribe to two-dimensional models of emotion, there are data suggesting that emotion space possesses a third dimension (Mehrabian, 1995b, 1996; Russell & Mehrabian, 1977; Youngstrom et al., 2003). This dimension has typically been labeled “dominance,” and it appears to relate to the degree of perceived control that the organism has over the emotion-eliciting situation. The dominance dimension separates fear (low dominance) and anger (high dominance; Mehrabian, 1996; Youngstrom et al., 2003), addressing one of the more problematic confluences of a two-dimensional model (e.g., Lavoie, Miller, Conway, & Fleet, 2001). The dominance dimension also separates confidence and pride from awe, suggesting that dominance is not simply a sub-factor of hostility splintering from negative affect.

Although research here is much sparser, there is evidence to suggest that a dominance dimension is also implicated in depression. Specifically, lower levels of dominance are associated with higher scores on measures of

depressive symptoms (Mehrabian, 1995a, 1997). In a three-dimensional framework, anxiety and depression share the negative/unpleasant valence and low dominance (i.e., submissiveness, in Mehrabian’s terminology) with anxiety disorders, including more arousal/activation (Mehrabian, 1997). The inclusion of a dominance dimension in models of depression is thought-provoking given recent attention to the role of submissiveness in the genesis of depressive disorders (Allan & Gilbert, 1997; Gilbert & Allan, 1998; Gilbert, Allan, Brough, Melley, & Miles, 2002; Gilbert, Allan, & Trent, 1995). Plutchik (1993) has speculated that depression would be associated with downward shifts in emotional dominance, and therefore decreases in perceived control of affectively salient cues would be linked to increases in depression. Dominance thus could provide a framework for integrating helplessness/hopelessness models of depression into an emotion model of psychopathology (Abramson, Metalsky, & Alloy, 1989; Seligman & Peterson, 1986).

Discrete Emotion Models

In contrast to the dimensional models discussed earlier, discrete emotion models emphasize the unique properties of distinct emotion systems. Discrete emotion models provide an opportunity for more textured analyses of behavior and neurophysiological underpinnings. At the same time, discrete emotion models entail considerably more complexity than two- or three-dimensional models of emotions, and it is important to determine that the increased complexity provides sufficient improvement in models of psychopathology to justify the adoption of less parsimonious models.

Current formulations of discrete emotions models emphasize that emotions and cognitions are reciprocally influential. Biological, temperamental differences in the emotion systems may be amplified or attenuated by environmental experiences, learning, and cognition. Izard (1977) has described “affective-cognitive structures,” patterns of spreading activation in neural networks that represent the amalgam of emotional and cognitive experiences. For example, there is an innate neural system responsible for the emotion of fear. Although all humans have the anatomical structures necessary for the experience of fear, individuals differ in their tendency to respond to environmental stimuli with fear. These differences are further shaped by learning history. Two children might witness the same car accident, yet one might respond with more severe and persistent anxiety due to a preexisting difference in temperament. In some situations, the environment and the emotional predisposition will combine to produce a new

tendency to respond differently to subsequent environmental stimuli.

In discrete emotions models, psychopathology represents the confluence of biological differences in emotion activation (forming a diathesis, or predisposition), coupled with environmental experiences and learned responses that generate stress. By dint of individual learning history, affective-cognitive structures can become quite complicated and idiosyncratic. In this regard, each individual's personal story and constellation of emotions and memories is unique. At the same time, certain discrete emotions are likely to be centrally involved in different forms of pathology. Fear is intrinsically linked to Panic Disorder, and disgust to simple phobias of spiders, snakes, and blood. Anger is more implicated in pathological expressions of aggression than would be sadness.

Patterns of Emotions in Depression

Discrete emotions models of psychopathology conceptualize disorders as involving constellations of emotions, or "emotion profiles." Some of the emotions are prototypically involved in the disorder, and others may only become attached to the affective-cognitive structure in a subset of cases. The "profiles of emotion" approach has been applied to both depression and anxiety disorders. The emotion profile involved in depression always involves high levels of sadness and diminution of happiness, joy, and pleasure. This has been found with self-report of discrete emotions in children (Blumberg & Izard, 1985, 1986) as well as adults (Clark, Watson, & Mineka, 1994). In addition, the profile of discrete emotions involved in depression often involves high levels of guilt, shyness, shame, and self-directed hostility. To some extent, elevations of these emotions reflect the involvement of general negative affect, as predicted and documented in the discussion of the tripartite model of depression and anxiety. Similarly, the hallmark features of high sadness and low happiness are consonant with the low PA or anhedonic component of depression.

However, a discrete emotions approach can inform models of depression beyond simply recapitulating a dimensional model such as the tripartite formulation. For example, a discrete emotions approach emphasizes the unique contribution of guilt to depression. Although there are a variety of discrete emotions that show strong factor loadings on NA (i.e., they involve high levels of activation and a negative valence), guilt shows a stronger relation to depression than do most other of the negative emotions. Indeed, excessive guilt is one of the diagnostic features of Major Depression according to the official psychiatric classification system (American Psychiatric Association,

2001). On the other hand, anger expressed outward appears to be less commonly associated with depression, and contempt toward others also appears to play a diminished role in depression. These are theoretically interesting inasmuch as they are exceptions to a simplistic "depression involves increases in negative affect" model. They also are consistent with models that make the approach/withdrawal distinction: Depression involves an increase in withdrawal-related emotions (shyness, sadness, guilt) and a decrease in approach-related emotions (e.g., happiness, affection, and anger).

Discrete emotions also help to cleave disorders into distinct entities. Anxiety and depression show distinct profiles, for example. Although both anxiety and depression involve substantial activation of negative emotions, depression is characterized by marked sadness and a lack of positive affect, whereas anxiety is signified by higher elevations of fear and variable amounts of positive affect (Izard & Youngstrom, 1996). In many cases, the heightened arousal of anxiety may be difficult to differentiate from anxiety, and part of cognitive therapy often involves reframing or relabeling diffuse arousal as excitement rather than fear (cf. Schachter & Singer, 1962). Further discrete emotions distinctions are discussed later.

At the same time, discrete emotions models also elaborate some of the commonalities between depression and anxiety. Both clearly involve high levels of trait inhibition (Kagan, 1994, 1997; Kagan, Snidman, Zentner, & Peterson, 1999), which also has been conceptualized as trait shyness (M. Lewis, 1995). Over the life span, inhibition and shyness are likely to be associated with trait neuroticism (Costa & McCrae, 1995; McCrae & Costa, 1986), which itself is a major associated feature of anxiety, depression, and psychopathology in general (S. J. Bradley, 2000; Zuckerman, 1999).

Profiles of Emotion and Manic Depression

Currently, there are no data to support a distinction between the emotion profiles of a unipolar depressive episode versus a depressed episode in the course of a bipolar illness. However, the emotion profile of a manic episode is clearly distinct. Hypomania and mania both involve high levels of interest-excitement and enjoyment. Indeed, "elated mood" is one of the cardinal features of manic episodes in children (Geller & Luby, 1997) as well as adults (Goodwin & Jamison, 1990). The grandiose component of the hypomanic or manic mood episode also entails feelings of self-assurance, confidence, pride, and potentially contempt and arrogance.

Most of these discrete emotions could be assimilated into a two-dimensional model of emotion and psychopathology. In a PA/NA model, mania would be described as involving extreme levels of PA activation. If one accepts the congruence of PA with Thayer's (2001) dimension of energy and with Gray's BAS, then the increased energy, excitement, and enthusiasm associated with hypomania and mania are also consonant with a two-dimensional model.

However, another prominent feature of mania is frequent irritability or rage. Irritable mood is one of the diagnostic symptoms of a manic episode, although *DSM-IV* stipulates that if mood is predominantly irritable instead of elated, then four other symptoms of mania must be present (instead of three; American Psychiatric Association, 2001). Irritability and rages are arguably the most prominent and impairing symptoms in juvenile presentations of Bipolar Disorder (Biederman, 1998; Carlson, 2002; Papolos, 1999). The centrality of irritability and anger to mania is a challenge to the PA-NA model of psychopathology, inasmuch as anger, hostility, and irritation are all classified as negative emotions, whereas mania otherwise appears to involve hyperactivation of the PA system.

The association of both anger and positive emotions with mania is less problematic for other dimensional models. In the BIS/BAS framework, both positive affect and instrumental or predatory aggression can be expressions of high BAS activation. Anger and irritability also are likely emotional responses to efforts to thwart or redirect the pursuit of goal-directed behaviors in a manic episode. Similarly, anger appears to involve increased left hemispheric cortical activation, consistent with its being an approach emotion in the approach/withdrawal framework articulated by Davidson and colleagues (Davidson, 1994, 2000; Henriques & Davidson, 1997; Tomarken & Keener, 1998). In a three-dimensional (PA, NA, dominance) emotion model, anger, irritability, grandiosity, and self-assurance are all high-dominance emotions, providing a theoretical context for the co-occurrence of these emotions in mania. Discrete emotions models also have no difficulty accommodating the distinct constellation of emotions that can be associated with mania, making a discrete emotions approach preferable to a simple two-dimensional model.

Differentiation of Discrete Emotions from Dimensional Models

Discrete emotions models of psychopathology have the potential to accommodate more textured descriptions of disorders than do dimensional models. Anger, for example, does not pose any special challenges to incorporation in a discrete

emotions model, because each emotion is posited to possess unique motivational properties (Izard, 1972). As discussed, the distinction between anger and fear is obscured by the valence-activation or PA-NA model of emotions.

Another potential distinction developed in the context of discrete emotion models is the differentiation of anger turned inward ("anger in" in Spielberg's, 1999, nomenclature, or "inner-directed hostility" in Izard's, 1972, formulation) versus anger overtly expressed toward another person or object ("anger out" for Spielberg; Spielberg, 1999; Spielberg, Reheiser, & Sydeman, 1995). Whereas anger out is a better predictor of verbal and physical aggression, anger in and inner-directed hostility are associated with depression (Blumberg & Izard, 1986; Izard, 1972; Izard & Youngstrom, 1996). Dimensional models can describe different forms of aggression, but they do not readily accommodate different forms of anger. For example, the Gray motivational model can describe three distinct motivational mechanisms for aggression: (1) defensive aggression in response to an imminent threat to oneself or extremely close others (motivated by the FFS); (2) predatory or instrumental aggression (motivated by the BAS); and (3) impulsive aggression (motivated by deficits in the BIS). However, it is not clear that all of these different forms would be associated with anger, nor do these descriptions of aggression capture the anger in versus anger out distinction.

A third, related issue that may be better resolved by a discrete emotions approach than a two-dimensional model of emotions has to do with emotion distinctions revolving around "perceived controllability" and dominance. Situational cues that activate the FFS could lead to either fear and flight or anger and defensive aggression. The difference between fear and anger in response to a threat will depend on the perception of controllability: Is the threat one that can be defeated or escaped? If it is judged (preconsciously) to be unbeatable, then the FFS will activate a fear response. Conversely, if the threat is vincible (or alternatively, inescapable), then the FFS will elicit the anger emotional system to motivate defensive aggression.

A fourth issue that is more adequately explained by discrete emotions than a dimensional approach pertains to the phenomenological characterization of anxiety disorders and their differences from depression as well as each other. PA and NA are not adequate to fully portray the differences between depression and anxiety, as recognized even in early formulations of the tripartite model (discussed earlier). Instead, a third dimension was invoked to more fully characterize anxiety disorders. This third dimension was initially

conceptualized as physiological hyperarousal, but subsequent studies that included discrete emotion measures demonstrated that fear was the discrete emotion most prominently associated with the physiological symptoms that were uniquely elevated in anxiety as opposed to depression. Further research on the anxiety disorders currently suggests that generalized anxiety disorder is the *DSM-IV* condition most closely associated with elevated NA (and also with higher trait neuroticism or BIS), whereas Panic Disorder is the condition most strongly linked to elevations in fear and physiological hyperarousal.

Simple phobias and Obsessive-Compulsive Disorder (OCD) also provide interesting examples illustrating the value of a discrete emotions approach. Although both phobias and OCD are considered anxiety disorders, the most pronounced emotional experience associated with many simple phobias, and with the contamination-oriented forms of OCD, is disgust. Phobias pertaining to snakes, spiders, and blood all involve an elicitation of disgust that is more marked than the fear or anxiety reported when people confront relevant stimuli (Davey, 1994a, 1994b; Davey, Buckland, Tantow, & Dallos, 1998; Davey, Forster, & Mayhew, 1993; Davey, McDonald et al., 1998). Similarly, disgust is the most elevated emotion in a profile of negative emotions activated in individuals suffering from OCD when imagining the object of their compulsions (Watson, 2000a). Thus, discrete emotions may prove useful in differentiating depression—which will include sadness and hypoactivation of positive emotions such as interest-excitement and happiness—from various anxiety disorders that may primarily involve elevations of NA generally (i.e., GAD), fear (i.e., Panic Disorder), or disgust (simple phobias, some OCD).

EXTERNALIZING BEHAVIOR PROBLEMS

Externalizing (or disruptive behavior) disorders include ADHD, Conduct Disorder (CD), and Oppositional Defiant Disorder (ODD), which are diagnosed in childhood and adolescence, and Antisocial Personality Disorder (APD), which is diagnosed in adulthood. Whenever possible, we discuss emotion processes as they relate directly to these disorders. Because little research examines emotion processes in populations meeting specific diagnostic criteria, most of this review focuses on emotion processes as they relate to the behaviors or personality traits that underlie these disorders. For example, disruptive behavior disorders are often characterized by aggression, hyperactivity,

impulsivity, and criminal behavior. In addition, these disorders are often associated with personality traits such as psychopathy and sensation seeking.

Each behavior or personality process associated with disruptive behavior disorders is likely to relate to somewhat different emotion processes. For example, the conception of impulsive aggression differs from current conceptualizations of psychopathic behavior. These constructs likely refer to differences in emotion regulation and associated structural and neurochemical impairments (Davidson, Putnam, & Larson, 2000). Even within a particular behavior, inconsistencies may exist. For instance, much research distinguishes between reactive and proactive aggression (e.g., Dodge & Coie, 1987), and their emotional correlates may differ. Reactive aggression is characterized by problems with anger expression and regulation, whereas proactive aggression appears to be motivated by negative approach emotions or callous and unemotional traits (Frick & Morris 2004; Loeber & Coie, 2001). Whenever appropriate, we highlight discrepant emotional correlates of disruptive behavior disorders and externalizing behavior problems.

The Developmental Functions of Emotions in Externalizing Behavior Problems

Abe and Izard's (1999b) review of the developmental functions of emotions and Lemerise and Dodge's (2000) discussion of the development of anger and hostility provide useful frameworks for considering how and when disruptions in emotional development foster the emergence and maintenance of externalizing problem behaviors. In infancy, anger expression, which can later become maladaptive, dysregulated, and prominent in many externalizing problem behaviors, fosters the development of autonomy and serves other adaptive functions in responding to discomfort and restraint (Abe & Izard, 1999b). Furthermore, interactions between infants and their caregivers provide the infants with their first opportunities to properly regulate emotions such as anger. Also, the emotional expressions that infants observe in adults provide the infants with their earliest source of information about the way emotional exchanges occur in the environment. Therefore, it is not surprising that beginning in early toddlerhood, children exposed to frequent angry maternal responses and interadult conflict are more likely to engage in noncompliant behavior (Crockenberg, 1985; Cummings, Iannotti, & Zahn-Waxler, 1985).

Beginning with the rapid increase in anger expression between infant and caregiver that coincides with the emer-

gence of locomotion (Campos, Kermoian, & Zumbahlen, 1992), angry and oppositional behaviors continue to increase throughout the 2nd year of life. During toddlerhood and the preschool years, children begin to acquire the capacity to use self-conscious emotions, particularly shame and guilt, which depend on at least a rudimentary awareness of self. The motivation inherent in these emotions and the associated capacity to respond empathically help children regulate anger and aggression (Abe & Izard, 1999b). Supporting the importance of self-conscious emotions and empathy for anger regulation, research conducted in childhood and adulthood shows that abundant shame, deficient shame-free guilt, and reduced empathy predict destructive responses to anger and psychopathic behavior (Barry et al., 2000; Tangney et al., 1996). It is likely that a maladaptive balance between shame and guilt and the reduced capacity for empathy begin to emerge by the preschool years.

By the end of the preschool years, angry and aggressive behaviors become less common, and those children who exhibit consistent negative emotionality are more likely to continue to display aggressive behavior (Eisenberg et al., 1996). As children enter elementary school, they begin to increasingly show the capacity for self-evaluative emotions, make self-comparisons, and engage in social perspective taking (Abe & Izard, 1999b). In light of these abilities, which hinge on engagement in the social world, the peer context becomes particularly important for gauging the development of inappropriate externalizing problem behaviors through middle and late childhood. Lemerise and Dodge (2000) noted that display rules become particularly salient during this period for peer situations involving anger. Not surprisingly, children who are not accepted by their peers tend to have difficulty managing their anger and, as a result, are more likely to make retaliatory responses (Bryant, 1992; Hubbard & Coie, 1994).

In adolescence, conflicting emotions and emotion patterns become more prominent, and adolescents with a more poorly developed sense of self and understanding of the complexity of personal relationships exhibit less positive emotion and more anger (Abe & Izard, 1999b; Hauser & Safyer, 1994). It is likely that consistent anger-driven peer difficulties, deficient empathy, and maladaptive patterns of self-conscious emotions emerging in childhood would contribute to a shallower personal and interpersonal understanding during adolescence. As a result, children with these difficulties are most likely to persist with retaliatory, aggressive behaviors and begin to exhibit the delinquent behavior associated with CD emerging in childhood, continu-

ing in adolescence, and possibly culminating with APD and more severe criminal behavior in adulthood.

Emotion-Cognition Relations and Externalizing Problem Behaviors

Two social cognitive models are particularly relevant to the discussion of emotions in externalizing behaviors: Crick and Dodge's (1994) reformulated social information processing (SIP) model and Baumeister et al.'s (1996) theory of self-esteem, emotion, and aggression and violence.

Crick and Dodge (1994) asserted that difficulties at any one of the six stages of their SIP model lead to maladaptive behaviors, and deficient processing at each step has a circular and reciprocal influence on the other steps. Their model receives much of its support from studies showing that children with "hostile attributional biases" (the tendency to attribute hostile intent to ambiguous peer situations in hypothetical vignettes, and the second step in the SIP model) tend to engage in more aggressive behaviors (Dodge, Price, Bachorowski, & Newman, 1990). The SIP model is now the dominant social cognitive model to describe the development of childhood aggressive behavior, although Crick and Dodge's reformulation of the model included little discussion of the role of emotion.

Lemerise and Arsenio (2000) sought to incorporate emotion processes into the SIP model. Their integrated emotional and social information-processing model added emotion processes such as emotion recognition, empathic responding, and the use of display rules to the reformulated SIP model. In support of the Lemerise and Arsenio model, recent evidence shows that emotion perception biases predict aggressive behavior in children and social information processes mediate the relation between emotion knowledge and aggressive behavior (Dodge, Laird, Lochman, & Zelli, 2002; Fine et al., 2004; Schultz et al., 2000). These findings suggest that basic emotion cue recognition and resulting perceptual biases are appropriately placed in the first step of the SIP model (Lemerise & Arsenio, 2000). Furthermore, children's emotionality may influence emotional aspects of social information processing. In a recent study, children's characteristic emotionality predicted their emotion perception patterns, and emotion perception partially mediated the relation between emotionality and aggression (Schultz et al., 2004).

Baumeister et al. (1996) asserted that, contrary to conventional wisdom, high self-esteem (not low self-esteem) in adolescents with a brittle ego is associated with interpersonal violence and aggression. They argued that high

self-esteem combined with situations of threat to a vulnerable ego bring about aggressive reactions through the mediating role of emotion. When criticized, people who have largely inaccurate and inflated views of themselves face an important choice. They must either reevaluate and change their self-appraisal or enter a shame-induced spiral to anger and, ultimately, aggression and violence. To support their theoretical assertions, Baumeister and colleagues cited empirical evidence of relations between unstable but high self-esteem and angry responses. They also cited evidence linking shame, anger, and aggressive responding (Tangney et al., 1996). Although the entire model has not yet been empirically tested, it is a noteworthy social cognitive model because it incorporates a self-conscious emotion (shame) into its conceptualization of aggression and violence. Therefore, this model fits well with the assertion that an important developmental milestone, the development of self-conscious emotions, may occur in a maladaptive manner and in certain circumstances lead to maladaptive patterns of externalizing behavior, including violence.

Emotion, Culture, Socialization Practices, and Externalizing Problem Behaviors

The vast majority of empirical research on the relations between emotion socialization and problem behaviors has focused on the family context, in particular, parental socialization of emotion. Eisenberg, Cumberland, and Spinrad (1998) provided a detailed discussion of parental socialization of emotion and a descriptive model where parenting practices predict specific emotion-related practices, which in turn predict aspects of children's emotional competence and later behavioral outcomes. Much research supports aspects of the model presented by Eisenberg and her colleagues. Specifically, family expression of positive emotions is associated with low levels of child aggression, and family expression of negative emotions is associated with increased levels of child aggression (Halberstadt, Crisp, & Eaton, 1999). More specifically, children exposed to conflict and anger between their parents are more likely to develop aggressive behaviors (Cummings, 1994). In recent research conducted by Eisenberg and her colleagues (Eisenberg, Gershoff, et al., 2001; Eisenberg, Losoya, et al., 2001), low levels of parental warmth as well as low maternal positive expressivity and high maternal negative expressivity predicted externalizing problem behaviors through their effects on children's ability to regulate attention and emotion.

Although extensive research has examined parental socialization practices, little research has examined cultural variation related to socialization of emotion or the impact

that the peer group may have on socialization of emotion. The small body of research that does exist suggests that there is some degree of cultural variation regarding the extent to which children are encouraged to express emotion. Specifically, a cross-cultural study showed that children in the United States were encouraged to express their emotions with more frequency than children in Japan, and the U.S. children also exhibited higher levels of aggression (Zahn-Waxler, Friedman, Cole, Mizuta, & Hiruma, 1996). Although not yet examined empirically, it is possible that different emotion socialization practices across cultures may explain part of the difference in levels of aggression and violent behavior among cultures.

Emotion Expression and Externalizing Problem Behaviors

Not surprisingly, the expression of anger is related to externalizing problem behaviors in numerous studies of children and adolescents (Cole, Zahn-Waxler, & Smith, 1994; Jenkins & Oatley, 1996; Keltner et al., 1995). However, the relation between anger and aggressive behavior is more consistent for boys and for children showing more reactive aggression than proactive aggression. In one study, preschool girls with externalizing problem behaviors tended to respond with less anger when placed in a disappointing situation (Cole et al., 1994). In another study, angry nonverbal behaviors in response to a laboratory-based game predicted reactive aggression but not proactive aggression (Hubbard et al., 2002). However, facial expressions of anger did not differentiate between reactive and proactive aggression.

Increased or decreased expressions of emotions other than anger also relate to externalizing problem behaviors. Adolescent boys with externalizing problem behaviors showed decreased facial expression of embarrassment (Keltner et al., 1995). Also, as previously mentioned, increased shame expression and reduced feelings of guilt are associated with anger-fueled destructive aggression (Tangney et al., 1996). Finally, reduced expression of guilt as well as an absence of empathy and the presence of emotions that are shallow and constricted were shown to relate to psychopathic behaviors in a sample of children (Barry et al., 2000).

Emotion Patterns in Externalizing Problem Behaviors

The previous section shows that other emotions besides anger relate to externalizing problem behaviors (Berkowitz, 1990), yet few studies have examined how these patterns of

emotions lead to these behaviors. Tangney and colleagues (Tangney et al., 1996; Tangney, Wagner, Fletcher, & Gramzow, 1992) provide preliminary evidence for the links between shame, shame-free guilt, anger, and destructive aggression. Shame-proneness was shown to predict anger, and shame-free guilt was generally inversely related to anger. More specifically, proneness to shame predicted responses to anger that were destructive and aggressive and resulted in negative consequences. Guilt, on the other hand, generally related to more constructive responses to anger, including taking corrective action and initiating discussion. These studies succeed in linking difficulties with self-conscious emotions and difficulties managing anger presumed to arise early in development with externalizing problem behaviors. Future research is needed to more specifically examine this pattern of shame, guilt, and anger as it emerges across childhood and as it relates to Baumeister and colleagues' (1996) social cognitive model of aggression and violence.

Emotion Knowledge in Externalizing Problem Behaviors

Although some community studies offer contradictory evidence (e.g., Izard et al., 2001), most studies of children with externalizing problem behaviors show deficient emotion knowledge and understanding of self and others (Arsenio, Cooperman, & Lover, 2000). Casey and Schlosser (1994) found that boys with externalizing disorders showed poor understanding of their own emotions when receiving praise from a peer. The boys with externalizing problems said that they expressed more positive emotion during the peer praise situation, but they had actually expressed more hostile emotion (anger, contempt, and disgust) than boys without diagnosed externalizing disorders.

Children with externalizing behavior problems also show poor understanding of other children's emotions. Children with ADHD or CD performed poorer than children without an externalizing disorder on a nonverbal emotion-processing task providing vocal and facial cues of emotion (Cadesky, Mota, & Schachar, 2000). However, children with comorbid ADHD and CD did not perform worse than children without an externalizing disorder. In another set of studies, a specific subset of children with externalizing problems, those presenting with "psychopathic tendencies," showed deficits in the recognition of fear or sadness in facial expressions and vocalizations (Blair, Budhani, Colledge, & Scott, in press; Blair, Colledge, Murray, & Mitchell, 2001; Stevens, Charman, & Blair, 2001).

Other studies show that children with externalizing problem behaviors may have a specific emotion perception bias which often leads them to interpret nonanger cues as expressions of anger. In studies of economically disadvantaged Head Start children, children who provided more anger responses to items where the correct answer was another emotion tended to show more aggressive behavior later in childhood (Fine et al., 2004; Schultz et al., 2000). Similar results were found in samples of middle-class elementary school children (Schultz, 2000; Trentacosta, Izard, Mostow, & Fine, 2001) and in children with CD (but not ADHD; Cadesky et al., 2000). Biased processing of nonanger emotion cues as anger cues may sometimes result from physical abuse that occurs early in childhood (Pollak et al., 2000).

Emotion Regulation and Externalizing Problem Behaviors

Deficits in emotion regulation, the ability to modulate an internal feeling and the related physiological process, are central to the development of externalizing problem behaviors. In a community sample of children, Eisenberg et al. (2000) showed that both the attentional (attention shifting and focusing) and behavioral (impulse control and behavioral inhibition) components of emotion regulation predict externalizing behavior problems 2 years later. As another example, children with ADHD combined type (but not inattentive type) exhibited emotion regulation deficits relative to comparison children without ADHD when completing a frustrating task (Maedgen & Carlson, 2000). Furthermore, children with ADHD were less able to manage their emotion expressions than comparison children even when given explicit instructions to mask their expression of emotion (Walcott & Landau, 2004). Other research suggests that emotion dysregulation mediates the relation between family and environmental factors, including maltreatment, harsh parenting, and violent victimization, and later aggressive behavior (Chang, Schwartz, Dodge, & McBride-Chang, 2003; Schwartz & Proctor, 2000; Shields & Cicchetti, 1997).

A related area of research focuses specifically on anger regulation and suggests that dysregulation of anger is predictive of externalizing problem behaviors. At age 3, boys who focused on the desired object during a frustration task showed increased anger (Gilliom et al., 2002). At age 6, boys who had engaged in this poor anger regulation technique were more likely to have externalizing behavior problems. On the other hand, boys who engaged in effective

anger regulation strategies, including distraction and passive waiting, showed fewer externalizing behavior problems 3 years later (Gilliom et al., 2002).

Recently, neuroscience research has increased our understanding of possible brain structures and circuits involved in emotion regulation. Davidson, Putnam, et al. (2000) specify a circuit most likely involved in impulsive aggression. Central to this circuit is the orbital frontal cortex (OFC) and the amygdala. The OFC relates to processes involved in reversal learning (altering an emotional response to a stimulus that received previous conditioning). The OFC and other structures in the prefrontal cortex provide inhibitory pathways to the amygdala. Therefore, impulsive aggression may result from impaired emotion regulation and, more specifically, disturbance in the OFC, amygdala, and related structures. As evidence, impulsive criminals show decreased PFC blood flow, and individuals with OFC lesions show increased impulsive aggression (Davidson, Putnam, et al., 2000).

The same emotion regulation circuit may not apply to psychopathic behavior and instrumental aggression (Blair, 2004). As evidence, “predatory” criminals did not show decreased lateral PFC metabolism (Davidson, Putnam, et al., 2000). Therefore, it is important to examine differences in brain functioning for psychopathic individuals. A recent study found that criminal psychopaths showed less emotion-related activity in the cingulate cortex as well as the amygdala (Kiehl et al., 2001). However, they showed greater activation than controls in areas of the frontal cortex. The results support the notion that psychopaths use more cognitive processing for emotional stimuli than nonpsychopathic individuals (Kiehl et al., 2001). These preliminary findings need to be replicated and extended to understand emotion regulation circuitry uniquely associated with psychopathic behavior.

AUTISM

Autism is a disorder marked by impaired social and emotional interactions (American Psychiatric Association, 1994). In 1943, Kanner first described autistic children as having “come into the world with innate inabilities to form the usual, biologically provided affective contact with people” (p. 250). Although much has been learned about Autism since Kanner’s original description, many theorists still focus on impairments in interpersonal relationships when conceptualizing autistic children’s core deficits (see Waterhouse & Fein, 1997, for a review) and when developing interventions for children with Autism (e.g., Bauminer,

2002). Similar to Kanner’s original conceptualization of autistic children as lacking “affective contact,” some theorists still believe that deficits in the emotion system are central features of Autism, contributing significantly to autistic children’s impaired social interactions. For example, Hobson (1993) proposes that children with Autism show severe abnormalities in innate emotion-related competencies necessary for interpersonal relationships, such as expressing, perceiving, and coordinating emotions with others; responding to others’ negative emotions; and showing appropriate awareness of self and others. Because autistic children have a greatly diminished capacity for “intersubjective engagement,” they fail to develop an understanding of others’ mental states or of their social world in general (Hobson, 1993).

However, other Autism theorists focus on the primary significance of other factors, such as problems with attention (e.g., Courchesne et al., 1994) or executive function skills (e.g., Ozonoff, 1995) when explaining autistic children’s social impairments. Regardless of the particular theoretical view, evidence strongly suggests that at least some emotion processes are affected in Autism. This section, devoted to the role of emotions in Autism, aims to describe differences in autistic children’s emotion systems and elaborate the connections between emotion system deficits and impairments in social functioning.

Developmental Differences

Consistent with the idea that emotions are particularly influential in the formation and maintenance of social relationships (Izard, 1991; Keltner & Kring, 1998), differences in the emotion systems of autistic children exert a negative influence on their social functioning and contribute significantly to the impaired social interactions that characterize Autism. Little is known about the development of discrete emotions in Autism. However, beginning early in the autistic child’s life, aspects of social development are abnormal. These developmental differences influence social interactions and emotional development as well.

One such developmental difference between individuals with Autism and typically developing children is the lack of joint attention behaviors observed in infants and children with Autism (e.g., Osterling & Dawson, 1994). Typically developing children engage in joint attention behaviors, such as looking at or pointing toward their caregiver when playing with toys, to focus their caregiver’s attention on an event or object. Such behaviors allow the child and caregiver to share play experiences. Furthermore, when a caregiver attempts to involve a child through pointing and

gazing, typically developing children tend to turn their attention toward the caregiver. Autistic children, however, rarely look to their caregivers when playing with toys, and they appear unable to follow others' pointing gestures or gazes (Sigman & Capps, 1997).

Because autistic children do not demonstrate joint attention behaviors, they are deprived of the opportunities of closeness and connection that such behaviors are intended to provide. Sharing play experiences provides rich opportunities for mothers and children to experience positive emotions together. According to differential emotions theory, sharing positive emotion is an important developmental task that functions to strengthen social bonds and build strong interpersonal relationships (Izard, 2002). Furthermore, empirical evidence suggests that early mother-child interactions involving shared positive emotions predict later positive socialization in typically developing children (Kochanska, Forman, & Coy, 1999). Autistic children's failure to experience positive emotion sharing through joint attention behaviors likely has far-reaching implications for their emotional development.

Also different among children with Autism is their failure to demonstrate social referencing behaviors. Unlike typically developing children who turn to their caregivers' faces when situations are ambiguous, children with Autism rarely look toward others' faces for information. This lack of social referencing behavior may indicate that children with Autism are not interested or able to read others' emotion expressions (Sigman & Capps, 1997). Autistic children's failure to show social referencing behavior limits the information available to them during ambiguous situations. More important, it also prevents them from learning about their world through others' emotional responses and deprives them from opportunities to share meaning with their caregivers (Sigman & Capps, 1997).

Language development is significantly impaired in children with Autism (see Lord & Paul, 1997, for a review). In typically developing children, language emerges from and utilizes preverbal forms of social communications, such as joint attention and social referencing behavior. Severely impaired in these basic skills, autistic children have communication difficulties throughout their lives (Sigman & Capps, 1997). Children with Autism seem especially impaired in pragmatics, the ability to use language in a socially functional manner (e.g., Baltaxa, 1977). Furthermore, children with Autism may have difficulty correctly using language relating to social relationships. For example, Hobson (1993) describes an individual with Autism who was unable to comprehend the meaning of the simple word "friend."

Delayed and atypical language skills may serve to hinder autistic children's emotional development. Because of their difficulty engaging in typical social discourse, children with Autism are at least partially deprived of the normative social conversations crucial for learning and communicating information, including emotion information. Failure to engage in emotion-related conversations furthers the autistic child's difficulty perceiving, interpreting, and utilizing emotion information.

Emotion-Cognition Connections

In addition to deficits in the emotion system, children with Autism also tend to show differences in their cognitive functioning. In fact, whereas some theorists conceptualize problems with emotions as the core psychological deficit in children with Autism, others believe that autistic children's primary impairment lies in social cognition or information processing (see Sigman & Capps, 1997, for a review). For example, researchers have focused on cognitive problems such as deficits in executive functions (e.g., Ozonoff, 1995), lack of a theory of mind (e.g., Baron-Cohen, 1995), and lack of central coherence in processing information (e.g., Frith, 1989) when describing the core deficits that characterize Autism.

Some theorists have hypothesized that the primary deficit in Autism is not merely emotional or cognitive, but instead derives from deficits in both the emotion and the cognitive systems (e.g., Sigman & Capps, 1997; Sigman, Dissanayake, Arbelle, & Ruskin, 1997). Specifically, Sigman and her colleagues speculate that autistic children's primary deficit is their lack of an integrated system of emotion and cognition. Empirical evidence also supports the theory that in autistic children, deficiencies in the emotion and cognitive systems are not independent (e.g., Buitelaar & van der Wees, 1997). Autistic children's deficits in both the emotion and cognitive systems can be conceived of as impairments in the development of adaptive emotion-cognition connections (Izard, 2002).

Typically developing children rapidly form connections between emotions and cognitions, beginning early in life (Izard, 1971). As children share affective experiences with others and learn to understand their social environment, these emotion-cognition connections enable them to act adaptively in their environment. Beginning in infancy, children with Autism are much less likely to share emotional experiences with others. Because of these missed opportunities, children with Autism gain less of an understanding of themselves, others, their relationships, and their societies (Sigman & Capps, 1997). In sum, children with

Autism miss out on valuable experiences that are fundamental to the development of healthy emotion-cognition connections. Without the emotion-cognition connections necessary for understanding and navigating one's social world, children with Autism have extreme difficulty.

Emotion Expression

Children with Autism were initially thought to exhibit affective "flatness" or "unresponsiveness" (e.g., Bettelheim, 1967). Although it is commonly recognized that autistic children do suffer from affective disturbances, theorists currently believe that these disturbances are not characterized by flatness. A number of empirical studies shed light on the actual differences in emotion expression in autistic children. One such study investigating parental perceptions of children's emotion expressions found that when compared to normal children, older, nonretarded autistic children expressed more negative emotions and fewer positive emotions (Capps, Kasari, Yirmiya, & Sigman, 1993). Specifically, parents reported that autistic children more frequently displayed sadness, fear, anger, shame, and guilt than typical children, and they less frequently displayed joy. Furthermore, according to parent perceptions, younger autistic children displayed more sadness and fear, as well as less joy and interest, than typically developing children (Capps et al., 1993).

In a similar vein, Yirmiya, Kasari, Sigman, and Mundy (1989) found that although young autistic children displayed positive emotions when interacting with parents and adults, they also expressed negative emotions more frequently than mentally retarded and typically developing children. Furthermore, more frequently than comparison children, autistic children displayed facial "blends," with part of their face expressing a negative emotion and part expressing a positive emotion. It is possible that autistic children display these facial blends when they find social situations confusing (Sigman & Capps, 1997).

Snow, Hertzog, and Shapiro (1987) compared autistic preschoolers to developmentally delayed preschoolers on a live interaction task with mothers, preschool teachers, and a child psychiatrist. Whereas the previously described studies found that parents described autistic children as expressing more negative emotions, the videotaped interaction paradigm revealed only fewer positive expressed emotions among autistic children. Negative affect, which was rarely expressed in either group, did not differ in frequency between the autistic and the developmentally delayed preschoolers. However, autistic children displayed positive emotions under different conditions than their de-

velopmentally delayed counterparts, such as when playing alone (Snow et al., 1987).

Interesting findings emerge from a pair of studies comparing autistic children to those with Down syndrome (Bieberich & Morgan, 1998, 2004). In the initial study comparing the emotion expressions of these two groups during a semistructured play situation with their mothers, children with Autism showed more negative affect and less positive affect than children with Down syndrome (Bieberich & Morgan, 1998). Although the authors found no differences in negative affect when the same groups were compared 2 years later, differences in positive affect remained. Specifically, children with Autism less frequently engaged in positive affect sharing (e.g., smiling, making eye contact, and actively engaging mother in play) than did children with Down syndrome (Bieberich & Morgan, 2004).

In contrast to the studies finding differences in frequency of positive or negative emotion expression, another study comparing facial expressions of autistic preschoolers to typical preschoolers found that both groups expressed both positive and negative emotions at similar rates (McGee, Feldman, & Chernin, 1991). For the majority of the time, both groups displayed neutral facial expressions. However, autistic children often expressed happiness, sadness, and anger at times incongruent to the specific situation. Similar to the study by Snow et al. (1987), whereas typical children showed happiness during peer or teacher interactions, autistic children expressed happiness when playing alone (McGee et al., 1991).

Although evidence conflicts as to the specific differences in autistic children's expressed positive or negative emotions, studies tend to agree that they do not show flat or unresponsive affect. Children with Autism do express emotions, though these emotions somehow differ from typically developing children, as well as other groups of mentally retarded children. Whether these differences reflect the amount of expressed emotion, the specific emotions activated, or the situations where they are expressed, they likely contribute to the impairments in social interactions characteristic of children with Autism.

Emotion Knowledge

The ability to perceive and interpret others' emotions are core facets of the broad construct of emotion knowledge (Izard, 1971, 1993). Studies suggest that autistic children may be at least somewhat limited in these competencies. However, the extent of these limitations is not well understood. The work of Hobson and colleagues suggests that

autistic children tend to have specific impairments in emotion knowledge skills. One such study showed that children with Autism had difficulty matching facial expressions with corresponding vocal expressions and bodily gestures typical of discrete emotions (Hobson, 1986). However, they were able to complete similar yet emotion-unrelated tasks, suggesting that their difficulty was specifically in coordinating emotion-related information.

In another early study by Weeks and Hobson (1987), children were instructed to match photographs of faces. Whereas nonautistic children tended to use emotion expressions to sort these photographs, children with Autism tended to group the photographs based on the type of hat worn in the picture (Weeks & Hobson, 1987). Furthermore, when the autistic children were asked specifically to match the photographs by emotion expression, many were not able to do so. Children with Autism may not only be less likely to utilize emotion information, they may also be unable to discriminate and perceive emotion cues (Sigman & Capps, 1997).

A study by Bolte and Poustka (2003) also supports the view that individuals with Autism have an impaired ability to recognize emotions. This study compared the performance of three groups, those with Autism, those with Schizophrenia, and an unaffected group, on a computer-based facial emotion recognition task. Individuals with Autism showed poorer performance on this task than the unaffected and schizophrenic groups. In addition, when examining the emotion recognition abilities of the autistic group's parents and siblings, performance was poorer in relatives from families with multiple autistic children than in families with only one autistic child. The authors conclude that deficits in detecting emotion facial cues are part of the endophenotype of Autism (Bolte & Poustka, 2003). Endophenotypes can be defined as "stable, heritable, quantifiable, endogenous characteristics that identify genetic risk" (Conklin & Iacono, 2003).

An additional study investigating emotion perception skills utilized a nontraditional procedure to further examine emotion recognition abilities of autistic children and adolescents (Celani, Battacchi, & Arcidianocono, 1999). This study included three groups of participants all matched on verbal mental age: individuals with Autism, individuals with Down syndrome, and a typically developing group. To assure that autistic individuals did not use "perceptual, piecemeal processing strategies" and instead used "holistic processing" when perceiving facial expressions, pictures of faces expressing happiness and sadness were presented for only 750 msec. After each face was presented, three additional faces were presented, and partici-

pants were asked to choose the photograph of the person with the same expression as was presented previously. On this "delayed-matching task," individuals with Autism performed worse than the groups of nonautistic individuals (Celani et al., 1999).

This study also investigated autistic individuals' tendencies to evaluate a face as pleasant based on whether it expressed happiness or a neutral expression. Whereas nonautistic groups preferred facial expressions of happiness, autistic individuals showed no preference for happy faces. These tasks suggest that individuals with Autism were less able to perceive and interpret the happy and sad faces than nonautistic individuals. The authors point out that although autistic individuals' ability to recognize emotions is not completely absent, the way they process emotion information may be qualitatively different from that of nonautistic individuals (Celani et al., 1999).

It is important to note that several studies have not found emotion perception deficits in autistic individuals, especially when groups are matched on verbal measures of mental age (e.g., Ozonoff, Pennington, & Rogers, 1990). However, given the aforementioned evidence, it is likely that autistic children do have at least some difficulty perceiving emotion cues in others. These limitations in emotion knowledge skills probably contribute significantly to their impaired social interactions. For example, if children have difficulty interpreting emotion information during a peer interaction, they may respond to peers inappropriately. Such inappropriate responses may lead to additional social mishaps and impoverished peer relationships.

Emotion theorists have long believed that emotion knowledge is a prerequisite for effective emotion communication. One cannot articulate or discuss emotion information, a component of healthy social interactions, without understanding emotion cues. Therefore, it is important to examine whether autistic children's impairments in emotion knowledge also extend to specific difficulties with emotion communication. Although children with Autism show extreme socially related language impairments in general, it is useful to determine whether children with Autism are capable of communicating emotion information when specifically asked to do so.

Studies suggest that children with Autism are able to provide appropriate responses when asked to describe situations eliciting basic emotions, such as joy and sadness. However, when conceptualizing and describing "self-conscious" emotions such as pride and shame, which require an understanding of social norms and moral behavior (M. Lewis, 1993), these children appear to have more difficulty (e.g., Capps, Yirmiya, & Sigman, 1992).

In one study, nonretarded autistic children and typically developing children provided similar responses when describing situations evoking the simple emotion of happiness. However, in contrast to typically developing children, children with Autism never referred to birthday parties (Capps et al., 1992). Children with Autism also generally provided appropriate responses when describing experiences of sadness. However, interesting differences emerged when comparing autistic children's and typically developing children's responses to times they felt embarrassed and proud. When describing events evoking both embarrassment and pride, children with Autism required more prompts from the examiners and more time to respond. In contrast to the typically developing children, who provided different experiences for happiness and pride, one quarter of the autistic children described the same situation for both of these positive emotion experiences (Capps et al., 1992).

Furthermore, autistic children frequently described external, uncontrollable events and made fewer references to an audience when describing embarrassing situations. Failure to refer to an audience when recounting embarrassing events may stem from early deficits in joint attention and emotion-sharing behaviors, suggesting that autistic children may experience and develop emotions differently (Capps et al., 1992). Similarly, a more recent study by Hillier and Allinson (2002) found differences in high-functioning autistic children's understanding of embarrassment. In this study, children with high-functioning Autism had more difficulty distinguishing nonembarrassing from embarrassing scenarios compared to typically developing children. They also had more difficulty providing appropriate justifications for certain embarrassing situations (Hillier & Allinson, 2002).

In a similar vein, recent research also suggests that high-functioning children with Autism have a "less coherent" understanding of jealousy than typically developing children (Bauminger, 2004). Although the autistic children in this study expressed jealousy in similar situations as typically developing children, their jealousy-related behaviors were different, as was their understanding of the emotion itself. The author discusses the findings in terms of the gap between high-functioning autistic children's intact capacity to experience a socially mediated emotion and their impoverished ability to comprehend it (Bauminger, 2004).

In sum, children with Autism appear relatively competent in their ability to interpret and describe their own emotions. However, they show differences compared to typically developing children, especially when emotions

are complex and socially mediated. During actual social situations, when multiple social and emotion cues must be perceived and interpreted rapidly, it is likely that autistic children's differences in emotion understanding and emotion communication will lead to significant difficulties in social interactions (Capps et al., 1992).

Empathy

Because children with Autism have at least some difficulty with emotion perception and emotion communication, one may assume that they are less able than typically developing children to empathize with others' distress. Theory and research tends to corroborate this assumption. In explaining the autistic person's limited capacity to show empathy, Baron-Cohen (2002) theorizes that individuals with Autism have an extreme version of the male brain. Inherent in the male brain is the drive to "systemize," which refers to understanding the rules directing the behavior of a system, as well as predicting and controlling a system's behavior. This drive to systemize is in contrast to the female's drive to "empathize" (Baron-Cohen, 2002). Using the Empathy Quotient, a self-report questionnaire, Baron-Cohen and Wheelwright (2004) demonstrated that adult males score lower in empathy than adult females, and individuals with high-functioning Autism or Asperger's syndrome have an "empathy deficit" when compared to controls.

Empirical studies of autistic children also suggest decreased empathic responding. One study used a three-component model of empathy conceptualized by Feshbach (1982) to compare high-functioning autistic children and normal children (Yirmiya, Sigman, Kasari, & Mundy, 1992). The three components of empathy investigated were recognition and discrimination of others' affective states, affective perspective-taking ability, and emotional response (Feshbach, 1982). Typically developing children performed significantly better on all three components of empathy than autistic children, suggesting that empathizing with others is more difficult for children with Autism (Yirmiya et al., 1992).

In other studies, experimenters have created situations in which children's parents have feigned distress (e.g., feeling ill, accidentally hurting themselves with a toy hammer), and children's empathic responses have then been evaluated (Sigman, Kasari, Kwon, & Yirmiya, 1992). In these contrived situations, typically developing children and mentally retarded children looked at the distressed parent, appeared concerned and upset, and offered com-

fort. In contrast, children with Autism tended to ignore their parents' distress, failing to make eye contact with them or offer comfort and support (Sigman et al., 1992). Such behaviors suggest that compared to mentally retarded or typically developing children, children with Autism are less interested in or less responsive to others' emotional responses (Sigman, 1998).

Autistic children's lack of responsiveness cannot be explained by being unaware of or overly aroused by another's distress (Corona, Dissanayuke, Arbelle, Wellington, & Sigman, 1998). Whatever the reason for autistic children's lack of interest or responsiveness to others' emotions, it has significant implications for their emotional development. Without the interest or ability to interpret another's emotional response and evaluate it as similar to or different from one's own, it seems unlikely that children with Autism will grow to appreciate others' emotional experiences or learn more deeply about their own feelings (Sigman & Capps, 1997). Children with Autism do not appear able to, or interested in, using others' experiences as opportunities to further understand emotions.

Another study evaluated autistic children's responses to the distress of an unfamiliar adult and also to a loud, unexpected, ambiguous sound (Bacon, Fein, Morris, Waterhouse, & Allen, 1998). Results showed that low-functioning but not high-functioning autistic children were much less likely than children in the control groups to look at the distressed adults when the adults banged their hands, knees, or elbows on the table or wall, exclaiming "Ouch." Furthermore, both low-functioning and high-functioning autistic children failed to orient toward the adult in the room when they heard the ambiguous sound. Whereas children in control groups turned toward the adult for information, neither autistic group demonstrated this social referencing behavior. This lack of social referencing behavior suggests that children with Autism, whether high- or low-functioning, may simply not find others' emotion expressions interesting or informative (Bacon et al., 1998).

It seems likely that impoverished emotion knowledge, in addition to a diminished interest in gathering emotion information from others, may contribute to autistic children's difficulties communicating about emotions, empathizing, and responding appropriately to others' distress. One can assume that these difficulties hinder autistic children's ability to comprehend and navigate their social world. Furthermore, the reduced capacity to understand and express empathy prevents the autistic child from the positive social and emotional experiences inherent in providing comfort to others in need.

Neurobiological Processes in Emotion Regulation in Autism

In attempting to further understand the core deficits in Autism, researchers have tried to identify biological systems affected in individuals with the disorder. Much research focuses on brain systems underlying the emotional and social impairments present in Autism. In 1990, a network of brain regions connected to social cognition and emotion was proposed by Brothers. One such neural structure involved in responding to social and emotional information is the amygdala (Brothers, 1990), part of the limbic system. Because the limbic system (including the amygdala) has long been known to play a role in emotion, the emotional and social impairments present in individuals with Autism may reflect underlying dysfunction in this system.

Studies using various techniques to investigate the role of the amygdala in Autism provide convincing evidence that the amygdala is at least one of the neural regions that shows abnormal functioning in individuals with Autism (see Baron-Cohen et al., 2000, for a review). For example, studies have shown that nonhuman primates with lesions on the amygdala show changes in their social behavior similar to those seen in autistic individuals. These social behavior changes include social isolation, failure to initiate social transactions, and inappropriate responses to social gestures (e.g., Emery et al., 1998; Kling & Brothers, 1992). Furthermore, lesions to the entire amygdala caused a syndrome in monkeys called Kluver-Bucy syndrome (Aggleton & Passingham, 1981), a syndrome considered by some to be an animal model of Autism.

Additional studies using fMRI provide compelling evidence that the amygdala plays a role in perceiving social and emotion information and is impaired in individuals with Autism (Baron-Cohen et al., 1999). Adults with and without Autism Spectrum Disorders were asked to look at photographs of people's eyes and determine their thoughts or feelings. In contrast to control subjects, who demonstrated activation of the amygdala when processing information about emotions and mental states, subjects with Autism Spectrum Disorders did not show this amygdala activation (Baron-Cohen et al., 1999).

In another study, subjects with and without amygdala damage were given an emotion recognition task requiring them to interpret emotions from a picture of a full face and a picture of the eye region alone (Adolphs, Baron-Cohen, & Tranel, 2002). Subjects with unilateral and bilateral amygdala damage performed similar to controls when interpreting basic emotions. However, they performed significantly

worse than controls when attempting to interpret more “social emotions” (e.g., guilt, arrogance, admiration) from both the whole face and the eye region. These findings suggest that the amygdala is implicated in interpreting certain emotions related to social interactions, thereby supporting the theory of dysfunction in the amygdala among individuals with Autism (Adolphs et al., 2002). Furthermore, MRI scans of adolescents and adults with and without Autism showed that individuals with Autism had reduced volumes in the amygdala and hippocampus, possibly signifying that connections between limbic structures and other brain structures are underdeveloped (Aylward et al., 1999).

In further examining neural correlates, researchers compared fMRI results of children and adolescents with high-functioning Autism Spectrum Disorders with typically developing controls when matching and labeling emotion facial expressions (Wang, Dapretto, Hariri, Sigman, & Bookheimer, 2004). When matching emotion expressions, children in the Autism spectrum group showed more activity in the precuneus and less activity in the fusiform gyrus, an area commonly known for face identification, than typically developing children. Additionally, typically developing children showed more activation in the amygdala during the emotion-matching task, requiring more perceptual demands and therefore less conscious processing, than during the more cognitive verbal labeling task. In contrast, children with Autism Spectrum Disorders showed no difference in amygdala activation between the two tasks, suggesting differences in their neural networks when automatically processing emotion facial expressions (Wang et al., 2004). These findings support the hypothesis of abnormal amygdala functioning in autistic children and provide insight into additional brain regions implicated in Autism. Taken together, lesion and neuroimaging studies contribute evidence for neural correlates of Autism, including amygdala-related differences. However, research has been inconsistent, and further investigation is needed (Sweeten, Posey, Shekhar, & McDougle, 2002).

Current research also points to vagal pathways as playing a role in both normal social behavior and in the impaired social behavior present in Autism. The polyvagal theory distinguishes between primitive vertebrates, which have only an unmyelinated vagus, and mammals, which have both unmyelinated and myelinated vagal pathways (e.g., Porges, 2002). According to this theory, these pathways serve different functions and drive three different behavioral strategies: social engagement, mobilization, and immobilization. Unique to mammals, the Social Engagement System depends on myelinated vagal motor fibers and

includes neural structures related to emotional and social behaviors. This system can also involve a calm state. The Social Engagement System includes brain structures that control various muscles, such as facial muscles responsible for emotion expressions and middle ear muscles responsible for hearing human voices. These muscles enable mammals to observe social stimuli and actively engage in the social environment (Porges, 2002).

The polyvagal theory has clinical applications that have been employed in preliminary studies to address the social deficits in children with Autism. Specifically, an intervention has been designed that involves stimulating the “neural regulation of the Social Engagement System” (Porges, 2002, p. 10). The model on which the intervention was based assumes that children with Autism have a Social Engagement System that is intact both neuroanatomically and neurophysiologically. However, they have functional deficits in this system, including dysfunctional regulation of the somatomotor component (e.g., impaired facial expressions) and the autonomic component (e.g., difficulty maintaining calm states). Through stimulating the neural regulation of autistic children’s brainstems, social behavior should improve, as the system will begin functioning properly (Porges, 2002).

This intervention has used acoustic stimulation as the method of improving neural regulation, specifically, stimulating the middle ear muscles. Middle ear muscles are important in hearing human voices, but they cannot effectively filter out environmental sounds when neural tone is low. Regulation of these middle ear muscles relates neuroanatomically to regulating muscles that control facial expressions, as well as those controlling vocal intonation. Receiving the “acoustic stimulation” did, in fact, increase autistic children’s social engagement behaviors. Specifically, autistic children receiving the acoustic stimulation showed decreased sensitivity to sounds and increased sharing behaviors (Porges, 2002). In addition, parents of these children were less intrusive after the intervention (Porges, 2003).

Continued research into the specific emotional and social impairments that characterize Autism, as well as the neural structures that may contribute to them, should further our understanding of an extremely complex developmental disability. Increased understanding of the development of children with Autism will continue enabling theorists to translate theory into research-based interventions that aim to promote healthy emotional and social development for children and families facing the challenges inherent in this syndrome.

CONCLUSION

The flourishing of research on emotions over the past 2 decades has significantly affected virtually all areas of behavioral science, including developmental risk and psychopathology. Increasing knowledge of the experience-dependent nature of neurobiological development in the emotion systems has put the nature-nurture argument about causal processes in psychological disorders in a new perspective. Most scientists now recognize the interdependence of biogenetic and experiential factors in normal and abnormal development. Both genes and experience contribute to the development of a hardy personality characterized by positive emotionality, optimism, and socioemotional competence. Both types of factors influence the processes involved in developing a psychopathological condition characterized by negative emotionality, pessimistic or biased appraisal processes, and maladaptive behavior.

Emotion science can serve as a model for the increasingly popular multidimensional approach to research in psychopathology. Virtually all definitions of emotion acknowledge that it involves neural, psychomotor, and experiential components and that emotion typically exists in intimate interaction with perception and cognition. Thus, emotion is by definition a complex construct that requires cross-disciplinary, multilevel, and multidimensional investigations. The evidence reviewed in this chapter suggests that the same holds for any psychopathological condition.

Although we could examine only a limited set of disorders, we showed that emotions figure prominently in conditions ranging from infant stress disorders to internalizing and externalizing problems and Autism. In our analysis of depression, we found that various models hinge on concepts of emotionality and that each model may offer leads for further research.

Throughout the chapter we recognized both the intrapersonal and interpersonal functions of emotions. Though little research has specifically concerned this distinction in emotion functions, we propose that intrapersonal functions serve important roles in one's sense of well-being, whereas interpersonal functions relate to sociality and adaptive social behavior. We suggest that these two types of processes may figure differentially in various disorders, and yet, we recognize an element of arbitrariness in distinguishing between them. We doubt that all the functions of emotions fall into categories with hard boundaries.

Although we considered multiple approaches, the writing of this chapter was guided in part by differential emotions theory and a discrete emotions approach to the study

of psychopathology. Wherever possible we identified the role of specific emotions in particular disorders. At the same time, we emphasized the need to examine self-organizing patterns of emotions, a notion that may relate more closely to dimensional approaches to the study of emotion and psychopathology.

Finally, our discussion of emotions and psychopathology assumes some modularity and relative independence among emotion, cognitive, and behavioral systems involved in developmental processes. We see the study of the development of connections between these systems as paramount in advancing our knowledge of the field of psychopathology. Progress in our understanding of experience-dependent brain and neurobiological development has changed our conception of intersystem connections from one defined largely in terms of behavioral output to one that includes particular populations of synapses and neurons. We have also become more aware of the possibility that sensitive periods in early development may optimize the formation of certain adaptive connections between the emotions and other systems and that a harsh environment during these periods may increase the likelihood of serious psychopathology.

FUTURE DIRECTIONS

Undoubtedly, many of the exciting advances in the area of emotions and psychopathology will come from interdisciplinary or cross-specialty collaborative teams. All noteworthy theories of emotion recognize the critical role of research on emotion-related behavioral, cognitive, and neural systems.

We see emotion-perception, emotion-cognition, and emotion-cognition-action interfaces as hot topics for future research in both normal and abnormal development. These areas have already claimed the attention of interdisciplinary researchers. For example, they have pointed to cortical midline structures as junctures where interaction of perception, emotion feeling, and cognition mediate the development of emotion knowledge and self-reflective consciousness (Northoff & Bermpohl, 2004). These researchers, like other interdisciplinary investigators, necessarily build on the work of specialists that provided much of the content of this chapter.

Study of the various perception-emotion-cognition-action interfaces promises to increase our understanding of normal and abnormal development of emotion knowledge

and emotion regulation. We propose that such intersystem research will also improve our perspective on the development of relations among emotion vocabulary, emotion knowledge, and emotion regulation, and clarify the critical role of the first two in the growth of the third. Understanding the development of these key aspects of emotion competence should help in developing effective preventive interventions. In turn, evaluations of emotion-centered prevention programs can lead to refinements in emotion theory (Cicchetti & Hinshaw, 2002; Izard, Fine, Mostow, Trentacosta, & Campbell, 2002). Next, we detail potential advancements in basic research for particular developmental problems and suggest ways that evaluations of prevention and treatment programs for well-defined problems can enhance emotion theory.

Internalizing Behavior Problems and Psychopathology

Previous research indicates that emotion knowledge predicts internalizing problems across childhood (Fine et al., 2003), yet few programs specifically address understanding of emotion in treatment protocols (for an exception, see Kendall, Aschenbrand, & Hudson, 2003). Basic research should further investigate whether poor emotion knowledge predicts internalizing psychopathology generally or is specific to some internalizing problems but not others. Then specific prevention programs and treatments could incorporate modules on emotion knowledge. Outcome research could assess whether emotion knowledge improves with treatment and whether increases in emotion knowledge are necessary for reductions in internalizing problems, as emotion theory would suggest.

Additionally, more basic research is needed on developmental changes in emotion thresholds in children with internalizing psychopathology. For example, children at risk for depression may have a low threshold for experiencing sadness, and children at risk for Panic Disorder may have a low threshold for experiencing fear. Studies of emotion thresholds may help to explain the development of these affective disorders across childhood and adolescence. Also, the role of anger in internalizing problems is understudied. Anger has been related to depression (see Blumberg & Izard, 1986), and irritability can be a feature of Bipolar Disorder. However, it is still unclear how much the propensity to experience anger places children at risk for these disorders and how much anger is involved in other internalizing disorders (i.e., anxiety disorders). It would also be helpful to examine the presence of unique patterns of emo-

tions in the mixed states that characterize the bipolar mood disorders in children.

As interventions for internalizing problems are refined, we can begin to examine whether emotion regulation is an important part of the process of prevention and treatment of internalizing psychopathology. Specifically, do children need to experience and learn how to manage emotion during the intervention in order to reduce their internalizing psychopathology? The theory behind our prevention program for Head Start children (see Izard, Trentacosta, King, & Mostow, 2004) suggests that emotion regulation mediates behavioral outcomes, but only additional intervention effectiveness studies with follow-up assessments can answer that question and inform emotion theory.

Externalizing Behavior Problems and Psychopathology

Future basic research on emotions and externalizing problems must continue to distinguish emotional correlates of forms of aggression and inform the prevention and treatment of these problems. Some of these problems involve the development of the self-conscious emotions involved in moral development. Both guilt and empathy, and probably shame as well, are absent or underdeveloped in children with strong psychopathic tendencies. Frick (2004) and others found that children with psychopathic tendencies have callous or "unemotional" traits. Because the preschool years are a sensitive period for the development of self-conscious emotions and empathic behavior and for fostering the development of emotion competence, emotion-centered prevention and intervention programs may prove most beneficial in early childhood. Basic research, particularly with children at risk due to poverty, maltreatment, and other psychologically threatening conditions, should also be extended. For example, to understand what it means to have unemotional traits, brain imaging studies could examine whether children with these traits process emotional information in ways different from other children. The tendency to favor cognitive processing over emotional processing has been shown in psychopathic adults (Blair, 2003).

Evaluations of programs to prevent aggression, violence, and other externalizing problems can also inform research and theory on the role of emotions in the development of externalizing psychopathology. For example, many programs designed to reduce childhood aggression include anger regulation techniques. If the theoretical

distinction between reactive (anger-motivated) aggression and proactive (non-anger-motivated) aggression proves valid, then programs that focus primarily on anger regulation should reduce reactive but not proactive aggression. On the other hand, programs that focus on empathy training may reduce children's proactive aggression but not their reactive aggression.

Autism and Other Developmental Disorders

One avenue for refining our understanding of emotion-related functioning in children with Autism may be to explore similarities and differences in the emotion competence of children with high-functioning Autism and those with Asperger's syndrome. Researchers could investigate whether children with high-functioning Autism and those with Asperger's syndrome (matched on intelligence) perform differently on emotion perception tasks. Given the previously established links between children's verbal ability and emotion knowledge (e.g., Izard et al., 2001), one may expect children with Asperger's syndrome to perform better in these domains. Such an investigation would add to the growing body of literature attempting to differentiate these two disorders (see Howlin, 2003, for a review).

Carefully conducted evaluations of prevention and treatment programs for children with Autism Spectrum Disorders would enable us to systematically explore the relation between emotion knowledge and peer relations that have been established in nonautistic populations (see Mostow, Izard, Fine, & Trentacosta, 2002). Intervention outcomes for existing programs targeting emotion functioning in autistic populations are emerging in the literature. For example, Bauminger (2002) evaluated a comprehensive cognitive-behavioral intervention targeting "social-emotional understanding and social interaction." The intervention found improvements in multiple areas of social functioning and some increased emotion understanding. Because explaining specific causes for positive outcomes can be complicated, future research should implement theoretically coherent emotion-based interventions and carefully evaluate them with matched control groups. With this methodology, we would have the opportunity to explore possible changes in emotion skills and subsequent improvements in social behavior and peer relations in children with Autism. Such a study could empirically test the hypothesis that even in autistic children, improved emotion knowledge and emotion regulation can translate into positive social outcomes.

REFERENCES 327

Starting as early as 3 to 6 months of age, infants begin to develop the remarkable capacity to coordinate their attention with a social partner in relation to some third object or event (D'Entremont, Hains, & Muir, 1997; Morales, Mundy, & Rojas, 1998; Scaife & Bruner, 1975). Bruner and Sherwood (1983) referred to this as joint attention skill development. In the 1st years of life, this involves the social integration of overt aspects of visual attention, as when a toddler shows a toy to a parent. Theoretically, though, this capacity is elaborated with development and comes to involve the social coordination of covert aspects of attention, such as when social partners coordinate attention to psychological phenomena, such as ideas, intentions, and emotions. Joint attention plays a role in many aspects of human social interaction, including when a 6-year-old child sits in class on the first day of first grade and tries to follow the attention and ideas of his teacher, or when a 16-year-old

child sits in the basement of her home in Moscow exchanging jokes with her friends, or when a 46-year-old father exchanges eye contact with his 14-year-old son to share his pleasure in witnessing beautiful waves breaking off the north shore of Kauai. Indeed, processes involved in joint attention contribute to social interactions, social learning, and social cognition across the life span (Baldwin, 1995; Mundy, 2003; Tomasello, 1995).

Theory and research on this domain have most frequently focused on the relations of joint attention to language development and social cognition in young children (e.g., Bruner, 1975; Carpenter, Nagell, & Tomasello, 1998). This perspective has been productive and has provided new insights into the nature of early atypical, as well as typical, development (e.g., Baldwin, 1995; Carpenter et al., 1998; Corkum & Moore, 1998; Morales et al., 1998; Mundy & Neal, 2001; Sigman & Ruskin, 1999; Ulvund & Smith, 1996; Yoder & Warren, 2002). However, what may be less well recognized is that, in addition to social cognition, joint attention development also reflects a developmental integration of social executive

The preparation of this chapter was supported by a grant from NICHD to the first author (RO1 HD38052).

and social motivation processes (e.g., Mundy, 1995, 2003; Mundy, Sigman, & Kasari, 1993; Sigman, 1998). Moreover, this integration of early executive, motivation, and social-cognitive processes suggests that infant joint attention may be fundamental to the development of social competence in childhood, as well as developmental psychopathology (e.g., Goldsmith & Rogoff, 1997; Mundy & Willoughby, 1996, 1998; Sheinkopf, Mundy, Claussen, & Willoughby, 2004).

Over the past 2 decades the importance of comprehending the foundations of social competence has become increasingly clear to clinical and developmental science. Social competence contributes to a wide array of adaptive outcomes among children, from school readiness and academic success (Blair, 2002; Raver, 2002) to risk and resilience in the face of vulnerability for developmental psychopathology (Masten & Coatsworth, 1998). Social competence, though, is a complex construct. Definitions typically emphasize a capacity for a prosocial behavior style that involves numerous processes, including (1) the ability to regulate attention and emotional reactivity in the dynamic flow of social interaction; (2) the ability to self-monitor, correct errors, and integrate the behavior of self with others in positive goal-related activity; and (3) the tendency to express agreeableness, interest in others, and positive emotions with peers and adults (Eisenberg et al., 1997; Masten & Coatsworth, 1998; Rothbart & Bates, 1998).

One approach to the study of social competence has been to define and measure processes in infancy that presumably contribute to the foundation for the subsequent mature expression of facility with social interaction and exchange. In this regard, research has most frequently concentrated on attachment and related patterns of early parent-child interactions, as well as investigations of temperament to understand the development of emotional and self-regulatory processes that emerge in the first few years of life (e.g., Calkins & Fox, 2002; Fox, Henderson, Rubin, Calkins, & Schmidt, 2001; Kochanska, Murray, & Coy, 2000; Masten & Coatsworth, 1998; Rothbart, Posner, & Rosicky, 1994). These avenues of research have provided powerful insights into the nature and development of social competence (Masten & Coatsworth, 1998). However, the complexity of this domain is such that additional lines of inquiry are required to fully understand the factors involved in socially competent behavior. In this regard, we suggest that measures of infant joint attention skills development provide information about early social communicative, social emotion, and social-neurodevelopment that are indispensable to a veridical understanding of human social competencies.

Several different forms of joint attention typically develop in the 3- to 18-month period of infancy (Bates, Camaioni, & Volterra, 1976; Carpenter et al., 1998; Seibert, Hogan, & Mundy, 1982). One form involves the infant's ability to follow the direction of gaze, head turn, and/or pointing gesture of another person (Scaife & Bruner, 1975). This behavior may be referred to as the "responding to joint attention" skill (RJA; Mundy et al., 2003; Seibert et al., 1982). Another type of skill involves the infant's use of eye contact and/or deictic gestures (e.g., a pointing or showing) to spontaneously initiate coordinated attention with a social partner. This type of protodeclarative act (Bates et al., 1976) may be referred to as the "initiating joint attention" skill (IJA; Mundy et al., 2003; Seibert et al., 1982). These behaviors, especially IJA, appear to serve social functions. That is, the goal and reinforcement of these behaviors seem to revolve around the sharing of experience with others and the positive valence such early social sharing has for young children (Bates et al., 1976; Mundy, 1995; Rheingold, Hay, & West, 1976). Alternatively, social attention coordination may also be used for less social but more instrumental purposes (Bates et al., 1976). For example, infants and young children may use eye contact and gestures to initiate attention coordination with another person to elicit aid in obtaining an object or event. This may be referred to as a protoimperative act (Bates et al., 1976) or "initiating behavior regulation/requests" (IBR; Mundy et al., 2003). This chapter focuses on these three types of behaviors, which are illustrated in Figure 9.1.

There are at least five distinct but overlapping strands of theory that forge connections between joint attention and the subsequent development of social competence (Mundy & Willoughby, 1996, 1998; Sheinkopf et al., 2004). Perhaps the most obvious notion is that joint attention is related to language development (e.g., Baldwin, 1995) and language development is related to social competence (e.g., Baker & Cantwell, 1987; Beitchman, Hood, & Inglis, 1990). Therefore, joint attention may be related to the development of social competence in children as an epiphenomenon of its relations to language development. However, longitudinal research suggests that, even after controlling for variance associated with differences in language development, infant joint attention predicts differences in the development of preschool to school-age social competencies in samples of typically developing children, as well as "at risk" and developmentally disordered children (Acra, Mundy, Claussen, Scott, & Bono, 2003; Lord, Floody, Anderson, & Pickles, 2003; Sheinkopf et al., 2004; Sigman & Ruskin, 1999; Vaughan et al., 2004). Clearly, other avenues of connection between joint attention and social outcomes

Figure 9.1 Illustrations of (a) responding to joint attention-RJA; (b) initiating joint attention-IJA, “pointing;” (c) IJA, “alternating gaze”; and (d) initiating behavior regulating/resuests-IBR, “pointing” from the Early Social Communication Scales. *Sources:* From “Assessing Interactional Competencies: The Early Social Communication Scales,” by J. M. Seibert, A. E. Hogan, and P. C. Mundy, 1982, *Infant Mental Health Journal*, 3, pp. 244–245; and *A Manual for the Abridged Early Social Communication Scales (ESCS)*, by P. Mundy et al., 2003, available from the University of Miami Psychology Department, Coral Gables, FL, at pmundy@miami.edu.

need to be considered. Therefore, after reviewing the longitudinal data on this issue, research and theory connected to four complementary and related models of the links between infant joint attention and social competence are examined. These models of joint attention development are (1) the caregiver/scaffolding model (e.g., Bakeman & Adamson, 1984; Bruner, 1975; Siller & Sigman, 2002; Tomasello & Farrar, 1986), (2) the social-cognitive model (e.g., Baron-Cohen, 1995; Bretherton, 1991; Bruner, 1975; Tomasello, 1995), (3) the social motivation model (e.g., Dawson, Munson, et al., 2002; Hobson, 1993; Mundy, 1995; Trevarthen & Aitken, 2001), and (4) the neurodevelopmental executive function model (e.g., Dawson, Munson,

et al., 2002; Griffith, Pennington, Wehner, & Rogers, 1999; Mundy, Card, & Fox, 2000; Vaughan & Mundy, in press).

This chapter examines the nature and validity of these models. Prior to arriving at this appraisal, a more concrete sense of our view of the fundamental linkage between infant joint attention and social competence may be better appreciated if one considers the following assertion. Joint attention measures provide an index of individual differences in processes associated with the capacity of infants (and ultimately children) to pay attention to what others attend to and to share experiences in social interactions (see Figure 9.1). As noted earlier, we assume that the capacity to pay attention to what others attend to is essential to

adaptive participation in social interactions, not just in infancy but *throughout the life span*. Indeed, it is difficult to think of infants and children effectively participating in social learning opportunities with caregivers, peers, or teachers without sufficient mastery of this capacity. Reciprocally, a disturbance in the tendency to attend to what others attend to may make important contributions to several forms of childhood psychopathology, such as Attention-Deficit/Hyperactivity Disorder (ADHD) and other externalizing disorders, as well as the Pervasive Developmental Disorders, including Autism. We believe that measures of joint attention provide a singularly important but relatively unrecognized window onto executive, motivational, cognitive, and environmental processes that early on contribute to stable differences in the development of social attention management and social competence throughout the life span. The primary goal of this chapter is to stimulate further thought and research on this assertion.

To this end, we must speak to the potential *incremental validity* of measures of infant joint attention in the study of social competence. Other measures of infant development have been both theoretically and empirically related to the development of social competence in childhood. As previously noted, these involve but are not limited to measures of infant attention management and related self-regulatory processes, attachment, empathy, and dimensions of temperament (e.g., Blair, 2002; Kochanska et al., 2000; Masten & Coatsworth, 1998; Rothbart & Bates, 1998). It makes little sense to champion the unique and vital contribution of joint attention research if measures of this domain simply provide an alternative route of access to processes that are well measured by more commonly used research paradigms. In this regard, we believe it is important to note that the ecological context of joint attention assessment is quite different from that of other attention management and self-regulatory measures in infancy. The latter often involve the observation of the behavioral activation or inhibition of children *in response* to externally imposed social task demands (e.g., Kochanska, Coy, & Murray, 2001) or to a social challenge, as in the Strange Situation attachment assessment paradigm (Ainsworth, Bell, & Stayton, 1972). However, mature social competence presumably involves the appropriate initiation of positive social behaviors, as well as appropriate responses *to* the social behaviors and demands of other people. Examining only behavior *responses* to task demands or social challenges may give an incomplete picture of processes involved in the development of social competence. Infant joint attention measures provide an important complement in this regard because they involve observations of the tendency of infants to

spontaneously initiate social attention bids in the context of semistructured interactions with others, as well as observations of the ability to respond to the social bids of a social partner (see Figure 9.1; Mundy et al., 2003). This facet of measurement may allow research on infant joint attention to provide a more complete picture of the potentially different motivation, self-regulatory, and social-cognitive processes involved in initiating and responding to social behaviors (Mundy, 1995, 2003; Mundy et al., 1993, 2000).

It is also important to recognize that measures of joint attention may be conducted in the context of either caregiver-infant interactions (Bakeman & Adamson, 1984) or infant-tester interactions (Seibert et al., 1982). By comparing responses and patterns of correlations across data from both paradigms it is possible to better understand which aspects of social competence in infants are specific to interactions with their caregivers versus more general features of their social presentation that are expressed with strangers as well as familiar caregivers. Thus, it is possible to examine the generalizability of social processes associated with infant joint attention. This, as we will see, may be especially critical when examining the degree to which joint attention and attachment processes reflect unique or overlapping processes associated with the development of social competence in young children.

DEVELOPMENTAL PSYCHOPATHOLOGY AND JOINT ATTENTION

It is also an aim of this chapter to illustrate one of the distinguishing principles that guides research within a developmental psychopathology perspective. The developmental examination of maladaptive and psychopathological behaviors can elucidate disorders and is also integral to understanding the processes that are essential to human nature (Cicchetti, 1984, 1990; Rutter, 1986). This is very much the case with respect to understanding the fundamental importance of joint attention to human nature. Much of the theory described in this chapter initially grew out of our clinical research on Autism (e.g., Mundy & Sigman, 1989; Sigman & Capps, 1997; Sigman & Mundy, 1989).

Autism is a neurodevelopmental syndrome (Dawson, Webb, et al., 2002) personified by a robust disturbance of social competence with syndrome-specific deficits in joint attention skill development (Mundy & Sigman, 1989; Mundy, Sigman, Ungerer, & Sherman, 1986; Sigman, 1998). Attempts to better understand the connection between joint attention disturbance and impaired social competencies in children affected by Autism led to observations that young children's tendencies to initiate joint at-

tention (IJA) bids involved emotional processes as well as cognitive processes (Kasari, Sigman, Mundy, & Yirmiya, 1990; Mundy, Kasari, & Sigman, 1992). It also led to research demonstrating that individual differences in IJA were related to parents' perception of the social relatedness of their children with Autism, as well as parent reports of relatedness among children with typical development (Mundy, Sigman, & Kasari, 1994). These findings stimulated our initial theory on the points of continuity between infant joint attention and childhood social competence (Mundy & Willoughby, 1996, 1998), as well as a series of unique empirical observations on the continuity between joint attention and preschool or childhood social development that is described in this chapter (Acra et al., 2003; Sheinkopf et al., 2004; Sigman & Ruskin, 1999; Vaughan et al., 2003).

The presumptive biological nature of Autism also kindled efforts to understand the neurodevelopment of joint attention (Dawson, Munson, et al., 2002; Griffith et al., 1999; Hendersen, Yoder, Yale, & McDuffie, 2002; McEvoy, Rogers, & Pennington, 1993; Mundy et al., 2000). This, in turn, contributed to theory linking joint attention to frontal executive systems involved in self-monitoring (Mundy, 2003; Nichols, Fox, & Mundy, 2005), social motivations, and affective expressivity (Mundy, 1995; Venezia, Messinger, Thorp, & Mundy, 2004), or those systems involved in mediating sensitivity to the reinforcement value of social interactions (Dawson, Munson, et al., 2002; Mundy, 1995; Nichols et al., 2005) and self-regulation (Morales, Mundy, Crowson, Neal, & Delgado, 2005). The possible commonality between joint attention and these potentially frontally mediated processes provides a new and essential component to theory on the links between infant joint attention, social competence, and developmental psychopathology. Moreover, these observations, stemming from the initial study of Autism, open up new vistas on the nature of the neural systems and functions that may support the fundamental human capacity for experience sharing and cultural cognition (Mundy, 2005). The discussion of this new neuropsychological perspective on joint attention development takes center stage in one of the final sections of this chapter. In the concluding section, we further elaborate on this developmental psychopathology perspective by discussing how joint attention research and theory, stemming initially from considerations most relevant to Autism, may be brought to bear on other topics in child psychopathology, such as ADHD and risk and resilience associated with maltreatment.

Each of the topics introduced in the preceding sections of this chapter is discussed in more detail following an

overview of the nature and measurement of infant joint attention development.

JOINT ATTENTION: THEORY AND MEASUREMENT

The construct of joint attention has been a focus for research and theory for some time. In their attempt to understand symbolic development, Werner and Kaplan (1963) described one aspect of the environment that stimulated representational and symbolic development in infancy as the "primordial sharing" situation, in which an infant and social partner were aware of their common perceptions of the same object. Harriet Rheingold and her colleagues (1976) marveled at the change in social facilities that occurred as children increased their bids to share the experience of objects in the later part of the 2nd year. The work of these scholars, as well as several others, alerted many in the community of developmental scientists to the essential role that the emergent capacity for joint attention may play in early development. However, at least with regard to our own circumscribed efforts, the related but independent work of Jerome Bruner and Elizabeth Bates and their colleagues spurred much of our research and theory on this aspect of early development. Bruner (1975) suggested that any complete theory of language development, including modular theories (Chomsky, 1965), must recognize that infants become adept at social attention coordination and related social communication skills prior to the emergence of spoken words. In Bruner's view, these skills reflected the emergence of a general, non-linguistic cognitive platform that contributed to subsequent language development. This perspective was based on numerous empirical observations, including research that indicated that some infants as young as 6 months could follow the direction of gaze, head turn, and pointing gesture of a social partner (Scaife & Bruner, 1975). The later observation was rather unexpected because the prevailing notion at the time was that infants were egocentric and could not adopt the perspective of others until after the 2nd year of life (Piaget, 1952). Nevertheless, it is a replicable observation (Morales et al., 1998), with some recent studies suggesting that the incipient appearance of this skill may occur as early as 3 to 4 months (e.g., D'Entremont et al., 1997). Scaife and Bruner's paradigm for measuring gaze following became the template for one measure of infant joint attention, referred to herein as "responding to joint attention" (RJA, Seibert et al., 1982; see Figure 9.1a).

Concurrent with Bruner's contributions, Bates and her colleagues (Bates, Benigni, Bretherton, Camaioni, &

Volterra, 1979) borrowed from the study of linguistic pragmatics to develop a functional taxonomy of the different types of intentional, social communication bids that infants display. Bates et al. distinguished between behaviors infants used to initiate episodes of joint attention for declarative purposes (protodeclaratives) and behaviors used for instrumental or imperative purposes (protoimperatives). The implicit goal of declaratives is to share the experience of an object or event with a social partner, and the motivation or reinforcement of the behavior is thought to stem in large part from the visual regard or emotional response of the social partner to the child (Bates et al., 1976; Mundy, 1995). The prototypic behavior here is showing a toy to a partner; pointing and alternating eye contact may also be used for this protodeclarative function (see Figures 9.1b and 9.1c).

Instead of the social motivation to share experiences with others, protoimperatives are used to elicit assistance from a social partner in obtaining an object or an event. Here the reinforcement appears to be obtaining the object or event rather than the social regard or emotional response of the partner. Hence, the motivation and reinforcement for the development of this type of behavior is regarded as less social. The use of eye contact, reaching, and pointing to elicit aid in obtaining an object that is beyond the infant's grasp exemplify this type of behavior (see Figure 9.1d). The terminology used by Seibert et al. (1982) to refer to the former as "initiating joint attention" skills (IJA) and the latter as "initiating behavior regulation/requesting" skills (IBR) is used in this chapter. Most of the research and theory covered in this chapter pertains to RJA, IJA, and IBR.

Concurrent with the contributions of Bruner, Bates, and others, theory was emerging on an intrinsic motivation system for human relatedness and communication. Trevarthen and Hubley (1978) proposed a human motivational system basic to episodes of intersubjectivity or shared awareness with others. This motivation system guides goal-directed social behaviors from early infancy and is expressed in terms of two developmental stages involving "primary" and "secondary" intersubjectivity. Primary intersubjectivity occurs early on (0 to 6 months) and reflects an infant motivational system that promotes the tendency to use and respond to eye contact, facial affect, vocal behavior, and body posture in interactions with caregivers. This primarily dyadic interactive phase of social development provides the information and experience that, in combination with cognitive maturation, allows infants to begin to develop representations of self and other as having both distinct and shared affective experience. That is, they become capable of "secondary intersubjectivity," or a conscious

awareness of both self and other sharing an experience (Tomasello, 1995; Trevarthen & Hubley, 1978). The emergence of secondary intersubjectivity is thought to occur between 6 and 18 months and the experience of secondary intersubjectivity has positive reinforcement value for the child. Therefore, it also contributes to ongoing motivation for social interactions (Tronick, 1998).

In social interactions in the 9- to 18-month period, the capacity for secondary intersubjectivity increasingly supports infants' abilities to engage in intentional social communication with others, as evidenced by the more frequent and systematic use of eye contact, conventional gestures, and signal-repair strategies (Rheingold et al., 1976; Tomasello, 1995; Trevarthen & Aitken, 2001). Intentional participation in communication implicitly suggests that infants are aware that social partners have the mental capacity to receive and interpret communicative signals. Hence, the notion of secondary intersubjectivity has become central to much of the theory and research that emphasizes that infant joint attention skills reflect the incipient development of social cognition or knowledge about other people (e.g., Bretherton, 1991; Carpenter et al., 1998; Moore, 1996; Tomasello, 1995). This social-cognitive perspective on intersubjectivity and joint attention has become the prominent model for theory and research on this domain (e.g., Carpenter et al., 1998). Indeed, it may be so prominent that other important processes involved in this domain have received less attention than they warrant. The work of several research groups (Adamson & MacArthur, 1995; Kasari et al., 1990; Trevarthen & Aitken 2001; Tronick, 1998) reminds us that a consideration of motivational processes may be necessary to a veridical understanding of the role of joint attention in social development. Moreover, in addition to social cognition and motivation, there has been relatively little recognition of the possibility that joint attention development may also reflect the interplay of attention/self-regulation processes with social-cognitive and social-motivation processes (Dawson, Munson et al., 2002; Mundy et al., 2000). The result has been a lack of an integrated multiprocess approach to theory and research on joint attention. This may have reflected the nature of the goals, questions, and levels of measurement researchers have chosen to emphasize in their research.

Measurement Issues and the Self-Organizing Hypothesis

One principal goal of developmental research on joint attention has been to define the ages at which specific types of social attention coordination skills first emerge (e.g.,

Bakeman & Adamson, 1984; Butterworth & Jarrett, 1991; Carpenter et al., 1998; Corkum & Moore, 1998). Related to this approach has been the goal of better defining when social cognition truly emerges in infancy (Tomasello, 1995). Consequently, experimental and longitudinal research has often emphasized the analysis of age group differences and the use of categorical or ordinal measurement. In particular, researchers have utilized criterion-related mastery of one or another type of joint attention skill to separate children into groups: (1) those who appear capable of a specific aspects of joint attention and social cognition at a particular age and (2) those who do not appear capable of a specific skill at a specific age. For example, Carpenter et al. used criterion scores to rate the age of onset of joint attention skills in a sample of 24 infants in their seminal study of joint attention skills development. This is a viable and useful approach. It enabled these researchers to examine processes that were related to age-related shifts in joint attention development. However, all paradigms have strengths and weaknesses, and one weakness of this approach is that it fosters a discontinuous view of joint attention development. Criterion-referenced measures may encourage the view that joint attention skills are either present or absent in young children.

Within an age group, though, infants often display a significant range of individual differences on any measure of joint attention development (e.g., Carpenter et al., 1998; Corkum & Moore, 1998; Morales et al., 1998; Mundy & Gomes, 1998; Scaife & Bruner, 1975). For example, at 6 months of age infants display a range of RJA abilities (Morales et al., 1998). These skills may not be consolidated in a majority of infants at this time, so the *average* age of mastery of RJA may be after about 8 or 9 months (Corkum & Moore, 1998). Nevertheless, evidence of the development of this skill is clear in *some* infants at an earlier age. So, is the correct estimate for age of onset of this skill when some infants first display RJA (perhaps 6 months) or when most infants display this skill (perhaps 9 months)? Equally, if not more, important is the observation that after the onset of a joint skill for *most* children, such as pointing to share attention, infants display significant individual differences with regard to how frequently or consistently they use this skill in social interactions (e.g., Henderson et al., 2002; Mundy et al., 2000).

Some may argue that these individual differences reflect measurement error. However, several studies now indicate that observations of these individual differences carry meaningful information about early social development. Individual differences in the frequency and consistency of joint attention behaviors, especially IJA and RJA,

display significant levels of longitudinal stability or test-retest reliability in the 9- to 18-month period (Block et al., 2003; Mundy et al., 2000; Mundy & Gomes, 1998; Sheinkopf et al., 2004). The stability in IJA is even evident across different interactive partners (i.e., infant-tester versus infant-caregiver paradigms) in the 9- to 12-month period (Vaughan et al., 2003). As was noted earlier, individual differences in infants' expression of IJA, RJA, and even IBR also appear to be meaningfully related to later preschool cognitive and behavioral outcomes (e.g., Carpenter et al., 1998; Sheinkopf et al., 2004; Sigman & Ruskin, 1999; Ulvund & Smith, 1996). Hence it seems unlikely that individual differences in infant joint attention simply reflect measurement error.

Relatively little research has focused on examining the nature and meaning of individual differences in early joint attention. Indeed, the degree to which individual differences are considered to be an essential topic varies with the level of measurement employed in research. For example, when using dichotomous age-of-onset measures, Carpenter et al. (1998, p. 110) may have been quite correct in stating that

whereas such things as attention following . . . are very likely prerequisites of word learning and, therefore, should be related to the ability to acquire words, there is no reason to suspect that the age of emergence of these skills for a given infant should be related in a systematic way to the number of words an infant acquires.

However, a shift from a categorical (present or absent) level of measurement to the interval or ratio level of measurement involved in measuring the frequencies of joint attention behaviors displayed by infants (e.g., Mundy & Gomes, 1998) lends itself to a rather different perspective. Indeed, there may be fundamental reasons for the expectations that individual differences on measures of the frequency or consistency of use of joint attention bids should be related to the rate of lexical development, as well as other aspects of development in young children. This in part is because, beyond the measurement of social-cognitive maturational status, joint attention measures may also provide indices of critical features of the social interactive style of young children that play a *self-organizing* role in their development (Baldwin, 1995; Mundy & Neal, 2001).

Much of early learning takes place in unstructured or incidental social learning situations, and theory suggests that joint attention skills assist infants in organizing social information processing in these situations (Baldwin, 1995). In language learning, for example, much of early lexical acquisition takes place in unstructured or incidental social

learning situations where parents provide learning opportunities by referring to a new object or event, but infants need to discriminate among a number of potential referents in the environment to focus on the correct object/event in order to acquire the appropriate new word-object/event association. The correct discrimination among potential referents allows infants to avoid possible referential mapping errors (Baldwin, 1995). To improve the chance of correct discriminations infants utilize the direction of gaze of the parent (i.e., use RJA skill) to limit the number of potential stimuli to attend to and increase the likelihood of a correct word-learning experience (Baldwin, 1995). Similarly, when infants initiate bids for joint attention, the responsive caregiver may follow the child's line of regard and take advantage of the child's focus of attention to provide a new word in a context that maximizes the opportunity to learn (cf. Tomasello, 1995).

Beyond learning language, the self-organizing function of joint attention may also play an important role in social development. Theoretically, joint attention involves an integration of information about self-experience of an object or event with information about how others experience the same object or event. Therefore, the more frequently infants engage in joint attention, the more comparative social information they have for building richer representations of self and other (Mundy et al., 1993). Moreover, the more they engage in joint attention, the more practiced they become in the types of social attention management that is necessary for facile participation in social interactions. Finally, it is also the case that the positive affective component of initiating joint attention bids (see Figure 9.1) may contribute to a positive sense of relatedness between caregiver and infant. Therefore, some aspects of joint attention may serve to elicit positive nurturance from primary or secondary caregivers, which contributes to a decrease in developmental vulnerability among some at-risk groups of children (Mundy & Willoughby, 1996, 1998). Unfortunately, it may also be the case that a robust attenuation of joint attention leads to a severe impoverishment of self-organized social information processing that impairs typical early social behavior development, and even social neurodevelopment (Mundy & Crowson, 1997; Mundy & Neal, 2001). Hence, joint attention may be regarded as an early developing *self-organizing facility* that serves to elicit and/or organize social information input in a manner that optimizes early social learning and social development (e.g., Baldwin, 1995; Bruner, 1975; Mundy & Neal, 2001; Mundy & Willoughby, 1998). This hypothesis is consistent with the broader, long-standing notion that infants and chil-

dren may make substantial contributions to their own development (e.g., Bell, 1979; Sameroff, 2000; Scarr, 1992).

Several corollaries follow from this aspect of theory on joint attention development. If joint attention reflects a self-organizing facility in early development, then the more consistent or frequent use of joint attention skills may lead to more and clearer social learning opportunities for infants. Therefore, reliable or stable individual differences in the frequency of joint attention skill utilization by infants and children may be expected to relate not only to lexical development, but to a host of other developmental outcomes as well (Mundy & Gomes, 1998; Mundy & Willoughby, 1996, 1998). For example, it would seem at least plausible that the frequency or especially the consistency with which 5-year-olds use joint attention-related skills could contribute to their success in negotiating the new demands of teacher-related didactic social information flow in the classroom or the novel peer-related social information flow on the playground. It may well be that the 5-year-old who can consistently follow the attention of teachers and peers has an easier time adapting to the academic and social demands of kindergarten than does the 5-year-old who is less facile with this aspect of joint attention.

Second, this aspect of theory suggests it may be very important to understand the factors that contribute to individual differences in the frequency of joint attention during development. In this regard, it is possible that differences in frequency of use of joint attention may reflect differences in the consistency with which children utilize social cognition in social interactions. However, to the best of our knowledge, current theory on social cognition does not describe either the mechanisms or the phenomenology of the processes that would contribute to individual differences in joint attention utilization among children. Alternatively, research and theory on the social motivation processes derived from experience or temperamental factors, as well as the contribution of attention regulation and self-regulation for joint attention has been formulated in part based on attempts to understand individual differences in this domain of development, may contribute to differences in the tendency of infants and children to employ their joint attention skills (e.g., Morales et al., 2005; Sheinkopf et al., 2004; Vaughan et al., 2003). Thus, simply by moving from a level of measurement associated with questions about age of onset to questions about individual or clinical group differences, new and important perspectives on infant joint attention development may be revealed.

This chapter focuses on studies that employed the latter types of measures to examine individual differences in in-

fant joint attention development. Support for the self-organizing hypothesis of joint attention development is presented later in the chapter (e.g., Bono, Daley, & Sigman, 2004; Crowson, 2001), and the factors that give rise to individual differences in infants' frequency of use of different types of joint attention skills are considered.

MEASUREMENT ISSUES: CAREGIVER VERSUS TESTER-INFANT INTERACTION PARADIGMS

Another interesting measurement issue in joint attention research concerns the context of assessment. It was previously noted that joint attention might be assessed in an infant-caregiver interaction paradigm (Bakeman & Adamson, 1984; Tomasello & Farrar, 1986) or in the context of an infant-tester paradigm (Bates et al., 1979; Seibert et al., 1982; Wetherby & Prutting, 1984). The infant-caregiver interaction paradigm emphasizes dyadic measures of the duration or frequency of interactive episodes where both the caregiver and child are focused on the same object or event during a period of free play. These periods of infant-caregiver shared attention may be referred to as *episodes of joint engagement*. Hypothetically, because of the familiarity of the interactive partner, this paradigm may provide data on the optimal capacity of the infant to participate in joint attention or episodes of joint engagement. Indeed, in the period of development between 9 and 24 months, significant differences have been observed in the tendency for infant-caregiver dyads to engage in episodes of joint engagement (e.g., Carpenter et al., 1998; Thorp, 2005). However, because the level of measurement involves observations of the dyad (i.e., the behavior of both partners in semistructured interactions), it is often difficult to tease apart the contribution of infants and caregivers in understanding the causal influences that contribute to developmental differences in joint engagement.

Alternatively, in the infant-tester paradigm, the influence of the social partner on the infant may be reduced by training testers to use responsive but standardized patterns of interactive behaviors. For example, in the Early Social Communication Scales (ESCS; Mundy et al., 2003; Seibert et al., 1982), tester behavior is yoked to the infant's behavior. That is, during the assessment, the tester maintains neutral affect as much as possible and minimizes movements and verbalizations until the infant's direct communicative bids to the tester. Upon observing a bid from the infant, the tester responds warmly and enthusiastically, but briefly, and then returns to a neutral interactive and affective state. By minimizing movement, verbal behavior, and

affect until the infant bids, this paradigm presumably yields a clearer picture of differences in the infant's tendency to spontaneously initiate joint attention bids. However, it is possible that the novelty of interactions with the testers may attenuate social communicative behavior for some infants relative to their behavior in interactions with a caregiver. This concern is mitigated to some degree by the observation that infants in the 2nd year tend to display as many affective communicative signals to strangers as they do to their mother (Jones & Tarja, 1989).

Although both paradigms have been used for over 2 decades, little is known about the relations of data derived from infant-tester paradigms and infant-caregiver joint attention paradigms. Recently, however, significant but modest correlations were observed between the tendency to display IJA on the ESCS and infants' tendency to alternate eye contact between a caregiver and a common referent in episodes of joint engagement (Vaughan et al., 2003). There is also some evidence that differences among infants in the frequency and types of joint attention behaviors displayed on the ESCS predict subsequent dyadic measures of frequency or duration of episodes of joint engagement (Crowson, 2001; Markus-Meyer, Mundy, Morales, Delgado, & Yale, 2000). Furthermore, the tendency of infants to initiate joint attention on the ESCS has been observed to correlate with parent report of social behaviors in typical and at-risk infants (Acra et al., 2003; Mundy et al., 1994; Vaughan et al., 2004).

These data suggest that young children may display significant consistency in the degree to which they initiate and participate in joint attention with strangers and caregivers. The operative word here, though, is "suggests," as far too little work has been done on this vital issue to yield firm conclusions at this time. Nevertheless, recent research provides support for the reliability and validity of the type of infant-tester measures of joint attention that are the focus of discussion in this chapter. With this background in mind, let us begin a more detailed consideration of the role of joint attention in research on developmental psychopathology and social competence. Our own work in this regard began with research that attempted to better define the nature of the social impairments of Autism.

JOINT ATTENTION, AUTISM, AND DEVELOPMENTAL PSYCHOPATHOLOGY

Autism is a biologically based disorder that may be more prevalent than once thought, occurring at a rate of 3 to

6:1,000 (Dawson, Osterling, Rinaldi, Carver, & McPartland, 2001; Fombonne, 2003). It is characterized by impaired social and communication development (Bailey, Philips, & Rutter, 1996; Kanner, 1943). However, prior to the 1980s, very little empirical work had been undertaken to define the nature of the social impairments that were characteristic of these children (Howlin, 1978; Mundy & Sigman, 1989; Sigman, Ungerer, Mundy, & Sherman, 1987). This paucity of information contributed to what was initially a poorly developed diagnostic system for Autism. Indeed, 20 years ago there was only one descriptive item for the social deficits of Autism in the *Diagnostic and Statistical Manual of Mental Disorders III*, “a pervasive lack of responsiveness to others” (American Psychiatric Association, 1980), and this remained the sole criterion of the social impairments of this syndrome until late in the 1980s (e.g., American Psychiatric Association, 1987). This descriptor was too broad to provide diagnostic precision. Moreover, it appeared to be inaccurate, as research indicated that many children with Autism responded to structured social learning environments, reacted when imitated by others, and displayed attachment behaviors (Mundy & Sigman, 1989; Sigman & Capps, 1997; Sigman & Ungerer, 1984). The overly broad and inaccurate nature of this criterion likely contributed substantially to an underestimation of the prevalence of Autism (see Wing & Potter, 2002, for a related discussion). Indeed, it was only with the publication of the most recent nosology (e.g., American Psychiatric Association, 1994) that we have had sufficiently well-articulated diagnostic criteria to begin to provide a clear and comprehensive description of the social impairments of Autism.

Rather than displaying a “pervasive lack of responsiveness to others,” it has become clear that people with Autism display a *pattern of strengths and weaknesses* in the acquisition of social and communication skills, and this pattern changes with development (Mundy & Sigman, 1989). In part, this pattern of strengths and weaknesses in social communication is exemplified by a robust failure to adequately develop RJA and IJA skills. Alternatively, children with Autism are less impaired in IBR skills to communicate their instrumental needs (Curcio, 1978; Loveland & Landry, 1986; Mundy et al., 1986; Sigman, Mundy, Ungerer, & Sherman, 1986; Wetherby & Prutting, 1984).

Joint attention disturbance in Autism may be central to what Kanner (1943) described as the children’s inability to relate themselves in the ordinary way to people and situations. In particular, it seemed possible to us that an absence of the shared affective acknowledgment of objects or events

that is integral to IJA behavior in infancy (see Figure 9.1) contributed to a sense of “a lack of relatedness” that clinicians often used in making the diagnosis of Autism with young children (Mundy & Sigman, 1989). Subsequently, the notion that joint attention disturbance is central to the pathology of Autism has become incorporated into many diagnostic and screening instruments (Baron-Cohen et al., 1996; Charman, 1998; Lord et al., 1999; Stone, Coonrod, & Ousley, 2000). Indeed, research on joint attention served to identify and provide an operational definition of the social symptom criteria used in the fourth edition of the *Diagnostic and Statistical Manual*, such as “a lack of spontaneous seeking to share enjoyment, interests, or achievements with other people (e.g., by a lack of showing, bringing or pointing out objects of interest)” (American Psychiatric Association, 2000, p. 75).

Numerous detailed reviews of the research on joint attention and Autism are available (e.g., Charman, 1998; Leekam, Lopez, & Moore, 2000; Mundy & Burnette, in press; Sigman & Kasari, 1995), so we do not repeat these efforts here. In brief, though, observations suggest that joint attention disturbance may be manifest in children with Autism at least as early as between 12 and 18 months of age (e.g., Osterling, Dawson, & Munson, 2002; Swettenham et al., 1998). Although early on in life children with Autism display important deficits in both IJA and RJA skills, the impairment in RJA appears to remit to a significant degree with development (Leekam et al., 2000; Mundy et al., 1994). The impairment in IJA, however, remains robust even in older children (Baron-Cohen, 1995; Sigman & Ruskin, 1999). IJA deficits are related to cognitive and language outcomes in children with Autism (Mundy et al., 1991; Sigman & Ruskin, 1999), as well as parent reports of social symptom intensity (Mundy et al., 1994) and long-term social behavioral outcomes among children with Autism (Lord et al., 2003; Sigman & Ruskin, 1999). In addition, they also appear to be related to the tendency of children with Autism to express and share positive affect with others (Kasari et al., 1990). Interestingly, though, neither IJA nor RJA disturbance seems to be related to attachment in these children (Capps, Sigman, & Mundy, 1994), and many children with Autism do not exhibit evidence of disturbance relative to developmental control samples on measures of attachment (Sigman & Mundy, 1989). These observations were among the first to suggest that joint attention and attachment may reflect distinct developmental domains.

Although IJA may reflect a more robust locus of social impairment in Autism, this is not to say that delays in RJA

development are not important. Recent research suggests that RJA development may be critical to early intervention responsiveness in young children with Autism. Bono et al. (2004) followed the development of 29 children with Autism between approximately 4 and 5 years of age. Data on the amount of time children were in structured interventions per week were collected, as were data on joint attention using the ESCS. Data from standardized language assessments were also gathered. The results revealed that across this 1-year period, both IJA and RJA were significantly related to language gains. Surprisingly, though, amount of intervention was only weakly related to language gain across the 1-year interval. However, a significant conditional intervention effect was observed such that positive effects for intervention intensity on language were observed for children with better-developed RJA skills. Thus, the relative frequency or consistency of joint attention behaviors displayed by children with Autism may be a marker of individual differences in intervention responsiveness among these children. Such a possibility was anticipated by theory on the role of joint attention impairment as both a symptom of Autism and as part of the etiology of the developmental disorder of Autism (Mundy & Crowson, 1997). The findings of Bono et al., 2004 are also quite consistent with the hypothetical self-organizing function of joint attention, at least among children with Autism.

INFANT JOINT ATTENTION AND CHILDHOOD SOCIAL COMPETENCE: LONGITUDINAL STUDIES

Observations that joint attention impairments are integral to the social developmental disturbance of Autism are important for several reasons. They provide much needed information about the nature of this disorder that has contributed to improvements in the diagnosis and treatment of individuals and families affected by it (Mundy & Thorp, in press). Theoretically, these observations also support the hypothesis that infant joint attention reflects aspects of early development that are fundamental to the development of subsequent social competence in children. If this is true, then longitudinal research should reveal evidence of significant lines of continuity between infant joint attention and later measures of childhood social competence. Moreover, evidence of such links should be observable not only in samples of children with Autism but in other samples of children as well, including children with typical development; recent research suggests that this is the case. First,

we provide a more detailed synopsis of the longitudinal research on Autism cited in earlier sections of this chapter, then we consider research on at-risk and typically developing groups of infants.

In one of the first longitudinal studies to address this issue, Sigman and Ruskin (1999) followed a sample of 51 children with Autism for 6 to 8 years. At the beginning of this study, the children were 3 to 6 years old. They were assessed with the ESCS and other social-emotional measures, such as an index of empathy. Standardized cognitive and language data were also collected at the inception of this study. A variety of outcome data were collected, including measures of the frequency of initiations of play by the children with Autism with peers as an index of individual differences in social engagement. An important observation in this study was that IJA behavior in the children with Autism (as well as in a control sample) was a significant predictor of individual differences in social engagement 6 to 8 years later, even after considering covariance with language and cognitive development. Alternatively, RJA behavior was related to language but not to social outcomes in these children. In a related study, Travis, Sigman, and Ruskin (2001) also observed that measures of both IJA and empathy make significant concurrent contributions to the explanation of variance in the level of peer engagement and prosocial behavior in a structured task among higher-functioning 8- to 15-year-old children with Autism.

Similar to the data from Sigman and Ruskin (1999), longitudinal observations have recently been reported by Cathy Lord and her colleagues (2003). These researchers followed 95 children with Autism from 2 to 9 years of age. The intellectual and language levels of the children were assessed at the beginning of this study. Their social status was assessed with parent report on the Autism Diagnostic Interview (ADI) and with direct observations on the Autism Diagnostic Observation Schedule (ADOS). The ADI and the ADOS provide measures of IJA and RJA, in addition to composite social, communication, and repetitive behavior symptom domain scores. The IJA and RJA measures obtained from the ADOS are similar but not identical to those derived from the ESCS.

In their outcome assessments at age 9, Lord et al. (2003) used teachers' reported observations on the Penn Interactive Peer Play Scale (PIPPS; Fantuzzo et al., 1995) to assess social engagement and competence in the children with Autism. The PIPPS yields three factors: a prosocial Interaction measure, an avoidant Disconnection measure, and an externalizing Disruption measure that are combined into a total social engagement score. The results of the

study indicated that neither ADI nor ADOS domain scores predicted social interaction outcome scores in this sample. However, ADOS IJA item scores predicted PIPPS total social engagement scores above and beyond variance associated with Verbal IQ. Thus, two studies using related but different methods have indicated that IJA measures significantly predict individual differences in the long-term social outcomes of children with Autism (Lord et al., 2003; Sigman & Ruskin, 1999).

As noted, it is not clear whether the observations of Sigman and Ruskin (1999) and Lord et al. (2003) reflect a general developmental phenomenon associated with joint attention or one that pertains only to the development of children with Autism. A recent study by Sheinkopf et al. (2004) begins to address this issue. These authors reported data from a longitudinal study of 30 infants with in utero cocaine exposure. Joint attention skills (i.e., IJA, RJA, and IBR) were assessed with the ESCS at 12, 15, and 18 months, and composite (average) measures of these domains were computed. These children were participants in a preschool intervention program at the University of Miami (the Linda Ray Intervention Center; LRIC); therefore, it was possible to gather social outcome data from preschool teacher reports of peer-related classroom behavior at 36 months. These reports were gathered using the Adaptive Social Behavior Inventory (ASBI; Hogan, Scott, & Bauer, 1992), the PIPPS (Fantuzzo et al., 1995), and selected subscales from the Child Behavior Checklist/2–3 (CBCL; Achenbach, 1992). There was considerable covariance among the data from these convergent methods. Therefore, the data from these measures were combined to yield reliable teacher report indices of three dimensions of problematic and adaptive behavior: (1) A *Disruptive Behavior* score was derived by standardizing and calculating the mean of CBCL Aggression, ASBI Disrupt, and PIPPS Disruption scales; (2) a *Withdrawn Behavior* score was derived by standardizing and calculating the mean of CBCL Anxiety, CBCL Withdrawn, and PIPPS Disconnection; and (3) a *Positive Social Behavior* score was derived by standardizing and calculating the mean of ASBI Comply, ASBI Express, and PIPPS Interaction.

The results indicated that IJA, RJA, and IBR each made significant contributions to the prediction of Disruptive Behavior. IJA and RJA were negatively associated with teacher reports of more disruptive behavior, and IBR positively related to this dimension (Sheinkopf et al., 2004). The results also indicated that RJA was negatively associated with teacher reports of Withdrawn Behavior but positively associated with Positive Social Behavior. Thus, processes associated with IJA appeared to be associated

with decreased risk for externalizing disturbance in this sample. Processes associated with RJA were also associated with decreased risk for externalizing and internalizing disturbances and an increased likelihood of displaying what preschool teachers regarded as prosocial behaviors. Alternatively, it may have been that higher rates of IBR reflect an impulsive and object reward-driven style of behavior in this at-risk sample of young children that was associated with risk for externalizing disturbance. Finally, it is important to note that variance associated with cognition and language did not appear to mediate the associations between joint attention measures and social behavior outcomes in this study (Sheinkopf et al., 2004).

The Sheinkopf et al. (2004) study is perhaps the first to document continuity between joint attention development and childhood social development in groups of children other than those affected by Autism. However, it was not clear if the 36-month assessment in this study was too early to provide an optimal index of stable individual differences in the social outcomes of at-risk children. Preliminary results of a longer-term follow-up of LRIC children have been reported (Acra et al., 2003). In this study, outcome data were collected on 42 children at 6 to 7 years of age in first grade. Cognitive and language outcomes were measured with the Differential Abilities Scales (Elliot, 1990) and the Woodcock Language Proficiency Battery-Revised (WLPB-R; Woodcock, 1991). Social outcomes were examined with both teacher and parent report on the Social Skills Rating Scales (SSRS; Gresham & Elliot, 1990) and the Behavior Assessment System for Children (BASC; Reynolds & Kamphaus, 1992). The results indicated that joint attention measures were correlated with social outcomes as measured by both parent and teacher report data. Therefore, parent and teacher report data were combined into composite measures including a measure of Social Competence (parent and teacher SSRS Social Skills summary scores, BASC Adaptability summary scores, and BASC Social Skills summary scores) and a measure of Hyperactivity and Attention Problems (parent and teacher SSRS Hyperactivity scores, BASC Hyperactivity scores, and BASC Attention Problems scores).

Consistent with data reported by Sheinkopf et al. (2004), the zero-order correlations observed by Acra et al. (2003) revealed that 18-month IJA measures were positively related to first grade Social Competence but negatively associated with Hyperactivity and Attention Problems. Unlike the data from Sheinkopf et al., though, RJA was significantly associated with language development but not with social development in this study. Moreover, IBR displayed the same pattern of correlations as did

IJA. That is, IBR displayed a significant positive association with Social Competence and a significant negative association with Hyperactivity and Attention Problems. Not surprising, though, cognition, language, and especially reading ability were also significantly correlated with Social Competence and Hyperactivity and Attention Problems. Multiple regression analyses revealed that 18-month IJA, but not IBR, made a significant contribution to both first grade Social Competence and Hyperactivity and Attention problems, after variance associated with this aspect of development (e.g., reading ability) was considered. Thus, infant IJA was observed to be the most consistent longitudinal correlate of social behavior outcomes in a high-risk sample (Acra et al., 2003; Sheinkopf et al., 2004), just as it was in samples of children with Autism (Lord et al., 2003; Sigman & Ruskin, 1999). However, it was still not clear from these findings whether the nature of associations between infant joint attention and social outcomes was sufficiently robust to be observed in samples with typical development, or whether these associations were limited to samples with atypical development.

Data relevant to this issue have been presented in a study by Vaughan et al. (2004), who examined the development of 41 typically developing infants from 12 to 30 months of age. At 12 months, ESCS data were collected on joint attention development. At 15 months, parent report data on dimensions of temperament that were expected to relate to executive and affective processes associated with joint attention and social outcomes were also assessed (e.g., Inhibitory Control, Attention Shifting, and Social Fear). A standardized cognitive and language assessment was administered at 24 months. Finally, at 30 months, social outcome was assessed with parent report data on the Infant-Toddler Social Emotional Assessment (ITSEA; Carter & Briggs-Gowan, 2000), which provided scaled scores for Externalizing Behavior, Social Competence, Internalizing Behavior, and Dysregulation.

Consistent with Sheinkopf et al. (2004), the results of this study indicated that both 12-month IJA and RJA were significantly and negatively related to ITSEA parent report measures of Externalizing. More frequent infant IJA bids and consistent RJA trial performance at 12 months were associated with parent ratings indicative of children who displayed less evidence of difficulty with impulsivity, defiance, high activity, and aggression at 30 months. Vaughan et al. (2004) also observed that IJA was negatively correlated with Internalizing behaviors but was positively and significantly correlated with a measure of Social Competence at 30 months. The latter provides parent reports concerning compliance, attention regulation, emotional

awareness, and prosocial behaviors. Twelve-month IJA was significantly and positively associated with an index of cognitive development (Bayley Mental Index) at 24 months, consistent with previous reports of a link between infant IJA and childhood intellectual development (Ulvund & Smith, 1996). However, this association did not mediate the relation between IJA and social outcomes. Furthermore, 24-month parent ratings of temperament (e.g., Attention Regulation and Inhibitory Control) were significantly associated with 30-month ratings of social outcome on the ITSEA. However, neither IJA nor RJA was related to these 24-month temperament measures. Indeed, IJA, RJA, and Inhibitory Control had unique and significant paths of association with Externalizing. IJA and Inhibitory Control also displayed unique and significant associations with 30-month Social Competence.

Thus, the results of the Vaughn et al. (2004) study were similar to those of the Sheinkopf et al. (2004) study in that IJA and RJA were both related to social outcomes in the 2nd to 3rd year of life. Longer-term longitudinal studies of social outcomes in school-age children, though, suggest that IJA may have greater or more consistent predictive validity (Acra et al., 2003; Lord et al., 2003; Sigman & Ruskin, 1999). This pattern of data suggests that IJA and RJA may tap into distinct but overlapping constellations of processes that lead to differences in their predictive validity for social competence in childhood.

In the following sections, the nature of common and distinct processes that may serve to link infant joint attention with the development of social competence in childhood is considered in more detail.

UNDERSTANDING THE LINKS BETWEEN JOINT ATTENTION AND CHILDHOOD SOCIAL COMPETENCE

Several longitudinal studies provide some support for the contention that individual differences in infant joint attention are important and related to subsequent aspects of social competence and behavior disturbance in children. What processes, though, contribute to this important development link? One obvious possibility is that joint attention is associated with language development (e.g., Baldwin, 1995), and individual differences in language are associated with differences in social competence (Beitchman et al., 1990). This possibility, though, is mitigated to some extent by the observation that joint attention measures are related to social outcomes in children even after controlling

for variance in performance on standardized language and cognitive measures (Acra et al., 2003; Sheinkopf et al., 2004; Sigman & Ruskin, 1999; Vaughan et al., 2004). This issue has by no means been definitively addressed. Nevertheless, these observations suggest the need to look beyond language to identify other factors that may be involved. Indeed, as previously noted, there are at least four conceptual models that are useful in organizing research and theory: (1) the caregiving/scaffolding model, (2) the social-cognitive model, (3) the social motivation model, and (4) the neurodevelopmental executive model.

The caregiving/scaffolding model proposes that adult or caregiver contributions are essential to providing the types of organized and responsive social interactions that allow infants to develop joint attention skills (e.g., Bruner, 1983; Goldsmith & Rogoff, 1997) and to subsequently develop social competence in childhood (Masten & Coatsworth, 1998). Therefore, continuity in caregiver behavior may contribute to the connections between infant joint attention and later social competence. In the social cognition model, the development or maturation of the capacity to understand others' thoughts, intentions, and feelings is thought to be crucial to joint attention development (e.g., Bretherton, 1991; Tomasello, 1995), and that social cognition is also essential for subsequent social competence (Dunn, 1995). The social motivation model suggests that joint attention skills reflect sensitivity to the reward value of sharing with others (e.g., Dawson, Munson, et al., 2002; Mundy, 1995; Trevarthen & Aitken, 2001), and, because these motivational factors also play a role in the development of social competence, motivation processes contribute to the developmental linkage between these domains. Finally, the neurodevelopmental executive model is related to both the social-cognitive and social-motivation models. It holds that joint attention development may involve frontal and temporal cortical and subcortical attention control, emotion regulation, and even "social executive" functions that also contribute to social development and social competence. In particular, the social executive capacity to engage in integrated self and other behavior monitoring may be a component of joint attention, social cognition, and social competence (U. Frith & Frith, 2001; Mundy, 2003; Vaughan & Mundy, in press).

A more detailed analysis of each of these models is provided in the following sections of this chapter. We recognize, though, that these models do not necessarily represent mutually exclusive perspectives. Rather, they offer an organizational heuristic for describing what we know, and *don't know*, about the links between infant joint attention and social competence. Unfortunately, what we

don't know currently significantly exceeds what we do know about joint attention. What we do know (or at least suspect) is that each of these models contains more than a grain of truth about the nature of joint attention development. It will be in the recognition of their complementary nature, and their synthesis, that progress will be made in delineating how we become capable of finding common ground with the thoughts, feelings, and points of views of other people.

The Caregiving/Scaffolding Model

In his formulation of joint attention development, Bruner (1983) emphasized that early parent-infant interactions often occur within common "formats" or "routines" during which infants and caregiver are focused on the same object or event. These "joint engagement" episodes form a rich interactive context that may contribute to joint attention development in infants (Bakeman & Adamson, 1984). One hypothesis is that, during joint engagement episodes, caregivers "scaffold" the abilities of their infants well before their infants are capable of demonstrating independent joint attention ability (Bruner, 1983; Danis, Bourdais, & Ruel, 2000; Kaye, 1982). Scaffolding refers to a process by which a capable partner modifies a task according to the emerging abilities of the child, or the child's "zone of proximal development," so that the child may successfully complete the task and, in repetitions of this supported practice, come to develop the self-management capacity necessary to the independent expression of skills involved in successful task performance (Vygotsky, 1978). One method of scaffolding in joint engagement is evident when caregivers follow the focus of attention of their infant. Caregivers then can capitalize on the focus of interest of the child to provide new information about the shared focus of attention (e.g., an object or event label). Caregivers may also interact with the child around the shared focus of attention, such as when they make eye contact while imitating the infant's actions on the toy or affective reactions to the toy. Theoretically, this social interactive enrichment around an object that the infants are already motivated to explore stimulates their awareness of social attention coordination, which contributes to joint attention development.

There is ample evidence for the role of caregivers in scaffolding the joint attention abilities of their infants (e.g., S. Landry, Smith, Miller-Loncar, & Swank, 1997; Legerstee, Varghese, & van Beek, 2002; Raver & Leadbeater, 1995; Roach, Barratt, Miller, & Leavitt, 1998). In a seminal longitudinal study, Bakeman and Adamson (1984) ex-

amined infants' development of joint engagement with their mother and with peers from the ages of 6 to 18 months. They investigated "active" joint engagement, where infants appear to acknowledge social attention sharing by looking back and forth between their caregiver and the object or event that is the common focus for the dyad. They also coded "passive" joint engagement, wherein infants do not look to caregivers, but both interactive partners share a common focus. The results indicated that both passive and active attention sharing in joint engagement were significantly more likely to occur when infants played with mothers than with peers. These results suggested that caregiver behavior played an important role in the ability of the child to participate in joint engagement.

Research on the effect of following the attention of infant and language development is also consistent with the scaffolding model and suggests that the interactive strategy adopted by the parent can facilitate or interfere with language learning. In particular, caregiver language that follows the infant's current focus of attention appears to be important for language acquisition. Reporting on data from a sample of 10 infants between the ages of 14 and 23 months (mean age = 17.4), Tomasello and Farrar (1986) found that words referring to objects, which were already a focus of the infant's attention, were comprehended better than words heard while the examiner was trying to switch the child's attention. There were no statistical differences in regard to the effect on word production, which the adults attributed to shyness with strangers. Dunham, Dunham, and Curwin (1993) corroborated these findings in a series of controlled studies with twenty-eight 18-month-old infants. These findings also have been substantiated in investigations of unstructured mother-infant play interactions (e.g., Akhtar, Dunham, & Dunham, 1991; Laakso, Poikkeus, Eklund, & Lyytinen, 1999). In their longitudinal study of 24 mother-infant dyads, Carpenter et al. (1998) found predictive relations between 12- and 15-month maternal utterances that "followed in" to the infant's focus of attention and word comprehension as measured by the MacArthur Communicative Development Inventory (MCDI) at those same age points, as well as a predictive relation between 12-month maternal language following and 15-month MCDI language production.

Theoretically, if caregiver responsivity and scaffolding have an effect on infant joint attention development, and related caregiver behaviors are also associated with subsequent development of social competence in childhood, then it may well be that stable individual differences in caregiving contribute to a link between infant joint attention and

childhood social development. Surprisingly little research directly addressing this important possibility is currently available. Nevertheless, several studies indirectly bear on this hypothesis.

Research indicates that there are stable individual differences in terms of the degree to which caregivers and infants spend time in joint engagement interactions. In their longitudinal study of 24 infants from 9 to 15 months, Carpenter et al. (1998) found some evidence for both stability and continuity of maternal utterances that followed in to the child's focus of attention. Masur and Turner (2001) also found evidence for both stability and continuity for global ratings of maternal responsiveness in 20 mothers when their infants were 10, 13, 17, and 21 months. However, neither group of researchers controlled for infant behavior when assessing stability coefficients. This may be critical because infant maturation may also contribute to the tendency of dyads to engage in joint engagement. Indeed, in our own research, parent report of language ability as early as at 9 and 12 months predicted differences in the growth of the average duration of joint engagement episodes between 9 and 18 months in a large sample of typically developing infants (Thorp, 2005).

Other research has examined the links between caregiver behavior in joint engagement and joint attention development in Autism (Siller & Sigman, 2002). This study indicated that caregivers of children with Autism followed in to the attention focus of their children as much as did caregivers of children with developmental delay and caregivers of typically developing children matched on language capacities. Perhaps even more important, caregivers of children with Autism who showed higher levels of responsive "following in" behavior during joint engagement interactions had children who developed better joint attention and language ability over a period of years than children of less responsive caregivers. These findings suggest a developmental link between parental sensitivity and the child's subsequent development of joint attention skills in children with Autism. This may be an extremely important observation that has considerable applied value. For example, recall that IJA disturbance is a fundamental feature of Autism and reflects a lack of a tendency among children with Autism to spontaneously share their interest in objects and events with others. What constitutes the most effective approach to this fundamental feature of Autism? In some types of intervention with Autism, the therapist tries to direct the attention of the child to a task and to shape the behavior, through operant "discrete trial" training, to achieve some performance goal, such as providing an object label

on command (Lovaas, 1987). However, increasingly, interventionists recognize that, if the spontaneous generation of shared experience is an important goal for intervention, then it may be important to begin with the interests of the child. The rationale here is that, if a child does not first demonstrate an interest in an object, it is unlikely that an intervention procedure will be able to teach the child to share his or her interest with others. So several interventions now train parents and professional to follow the attention or interest of the child and to scaffold that unilateral interest toward social sharing. This requires a very different social-emotional orientation for the therapist (or parent) than is typically described in stricter behavioral intervention orientations. Nevertheless, evidence is beginning to emerge that this shared-attention scaffolding approach may be a very important component to effective intervention with young children with Autism (Greenspan & Wieder, 2000; Gutstein & Sheely, 2002).

Outside of research on Autism, several studies have suggested that general measures of caregiver social behavior and responsiveness are related to joint attention development. Wachs and Chan (1986) observed that a more positive social home environment was related to the development of IJA skills (protodeclaratives), but not to IBR skill development (protoimperatives). Flanagan, Copp, Riggs, and Alario (1994) reported that less responsive caregiving among teenage mothers was associated with better IBR development, and enhanced caregiver responsiveness was associated with better IJA development in their infants. Goldsmith and Rogoff (1997) carried out a seminal study in which they observed that dyads involving caregivers with depression were significantly less likely to enter into episodes of joint engagement than were dyads with caregivers who were not affected by depression. These studies used different methods and samples but consistently indicated that factors associated with the social responsiveness and the emotional quality of caregiving may impact joint attention development. These results are quite consistent with the scaffolding model. However, more research is needed to directly examine the degree to which specific types of scaffolding behaviors in caregivers may affect the development of joint attention in typically developing infants across the first and 2nd year of life.

Research on the connection of joint attention development with caregiver social behavior and responsiveness leads to another important possibility. If the development of joint attention is related to qualitative aspects of caregiving, then perhaps joint attention is significantly influenced by the attachment quality of infant-caregiver dyads. If so,

such a relation would be very important to consider in understanding the links between joint attention and outcomes. Several studies have provided data relevant to this issue. For example, previously reviewed studies indicate that a robust disturbance of joint attention (especially IJA) is characteristic of children with Autism. However, other research indicates that children with Autism display attachment behaviors that are quite similar to those exhibited by developmentally delayed control children (Sigman & Mundy, 1989; Sigman & Ungerer, 1984). This suggests that there is a dissociation between attachment and joint attention developmental processes in children with Autism. This view was supported by a study by Capps et al. (1994), which reported that, although IBR was a significant correlate of differences in attachment behavior in a sample of children with Autism, IJA behavior was not associated with attachment.

Does this mean that attachment and joint attention development are not strongly associated in other samples of children? An authoritative answer to this question is not yet at hand. However, it is noteworthy that relatively clear evidence of an association between attachment and joint attention has been revealed only in studies that have included observations of disorganized attachment. The latter refers to an atypical pattern of behavior that may be associated with poor if not abusive caregiving environments. Schölmerich, Lamb, Leyendecker, and Fracasso (1997) observed that, in a low-socioeconomic status sample, disorganized attachment status, but not avoidant or anxious-ambivalent attachment status, was related to the degree to which caregivers and infants entered into joint engagement episodes in social interactions. Claussen, Mundy, Malik, and Willoughby (2002) also did not observe an effect for secure versus insecure groups, but did observe an effect for disorganized attachment on joint attention development as measured on the ESCS.

In the Claussen et al. (2002) study, groups of infants at risk for cognitive and behavioral disturbance associated within utero cocaine exposure with either secure, insecure, or disorganized attachment status were compared on the ESCS at 12 and 18 months of age. The results revealed no effect of attachment on RJA but an attenuation of IBR and IJA development in the disorganized group. IBR development was lower for the disorganized group, but increased from 12 to 18 months. However, IJA bids actually decreased from 12 to 18 months in the toddlers from disorganized attachment dyads. One interpretation of these results is that less than optimal caregiving associated with disorganized attachment may lead to a general attenuation of the tendency of the toddler to initiate communicative

bids, but also a *reduction* over the 12- to 18-month period in the social motivation for secondary intersubjectivity, as measured by the development of IJA bids.

A similar set of observations has been provided in a study of children adopted from institutional orphanages in Asia at an adoption clinic at the University of Minnesota (Kroupina, Kuefner, Iverson, & Johnson, 2003). Infants entered these institutions shortly after birth, but many of these orphanages had few attendants. Therefore, although they provided for the physical needs of the children, they often provided minimal social-emotional nurturance. As children were adopted, they were brought to this country at different ages and after different lengths of stay in these institutions. They were administered the ESCS as part of a broader developmental assessment at the university clinic. The results revealed that age of adoption or length of stay in the orphanage did not have an effect on RJA or IBR development, both of which exhibited monotonic age-related increases. However, the age-related development of IJA was U-shaped such that, after about 14 months of living in the orphanages, the IJA development of the infants displayed a significant and systematic age-related decline. This profile of declining IJA skill is very similar to the pattern observed by Claussen et al. (2002) in their study of infants with substantial biosocial risk and disorganized attachment status. These data raise the possibility that there may be sensitive periods in which appropriate social stimulation or social reinforcement is needed to promote adequate development of joint attention in the 2nd year of life.

In another dissertation at the University of Miami, Block (2005) examined the association between attachment and joint attention in samples of typically developing infants from infant-caregiver dyads with secure or insecure, but not disorganized, attachment. This study observed little evidence of an association of secure or insecure attachment assessed with the Strange Situation paradigm at 18 months and infant-tester joint attention measures of development on the ESCS in the 2nd year of life. However, 12-month infants from dyads with secure and anxious-ambivalent attachment ratings exhibited more IJA bids to their mothers, who were seated in the testing room during the ESCS, than was the case for infants from avoidant dyads. These observations raise the possibility that attachment may be related to the specific expression of joint attention within the caregiver-infant dyad, but not necessarily to the general capacity of infants to engage in joint attention with other people, such as a tester in the ESCS. Interestingly, Block (2005) also observed a conditional effect such that infant IJA behavior was more strongly associated with 24-month cognitive/

language outcomes in children who displayed higher rates of behaviors associated with insecure rather than secure attachment in the strange situation. This observation is consistent with the relative vulnerability hypothesis of joint attention development (Mundy & Willoughby, 1996, 1998). This hypothesis acknowledges that caregiving may play a role in joint attention development. However, it stipulates that joint attention also reflects constitutional social motivation and executive functions (see subsequent sections), and these may serve to facilitate the capacity of infants to relate to others and self-organize positive social interactions. To the degree this is true, joint attention skills may serve to mitigate the developmental risk that ensues for some forms of less than optimal caregiving.

Additional evidence consistent with the self-organizing, vulnerability hypothesis has been presented by Crowson (2001). This study examined the relations between joint attention and 24-month outcome in 15-month-olds from either secure ($n = 22$) or insecure ($n = 21$) infant-caregiver attachment dyads. Twenty-four-month outcome in this study was measured in terms of performance on standardized measures of cognitive and language development, as well as with a measure of the tendency of toddlers and caregivers to engage in joint engagement in a 12-minute social interaction paradigm (Bakeman & Adamson, 1984; Tomasello & Farrar, 1986). Crowson found that RJA was related to cognitive and language outcomes in both groups. However, the relations of IJA to outcomes appeared to be conditional on attachment security. In the secure attachment group, 15-month IJA was not related to outcome. However, the tendency of caregivers to follow in on the line of regard of their infants to establish joint attention at 24 months was related to individual differences in language development, replicating earlier observations by Tomasello and Farrar. However, this maternal behavior was not related to language development in the insecure group, and the group difference in the size of this correlation was significant even though there was no difference in caregiver following in behavior across the groups.

Alternatively, in the insecure group, the tendency of infants to display IJA behaviors at 15 months (e.g., showing) with a tester was related to infants' tendencies to initiate joint attention in interaction with caregivers at 24 months, and both of these behavior tendencies were associated with language development in this group. These observations were interpreted to suggest that infants' ability to self-organize social information flow had relatively little impact in the context of the more optimal social learning environment that is presumably provided by responsive

caregivers in secure dyads. However, in insecure dyads, infants had more of the “responsibility” to create optimal social learning opportunities with their less responsive caregivers. In these dyads, IJA skills served to enable infants to engage their caregivers and self-organize social interactions in such a way as to optimize their development and to decrease the developmental risk incurred by the less sensitive caregiving that is associated with insecure attachment status. These are provocative results, but they need to be replicated before strong conclusions may be drawn.

What can be concluded from this research is that the social environment created by the caregivers may contribute substantially to joint attention development and its relations to outcomes. Direct observations of scaffolding as measured in joint engagement interactions likely provides one of the best means for evaluating the effect of caregiving on joint attention. Alternatively, measures of attachment may have a less direct and perhaps even non-linear relation to infant joint attention development. However, we know all too little about caregiver-child interactions in joint attention development. More work of this kind is needed, and it may have ramifications for both basic and clinically relevant research issues on joint attention development.

There are also good reasons to believe that the perspective of the caregiving model alone does not provide a complete picture of the links between infant joint attention development and social outcomes in children. For example, caregiving factors have been related to the development of IJA (e.g., Claussen et al., 2002; Wachs & Chen, 1986) but not so clearly to RJA (e.g., Claussen et al., 2002; Crowson, 2001; Kroupina et al., 2003). However, there is at least as much evidence that RJA is connected with the development of social competence in childhood as there is evidence of a link with IJA (Sheinkopf et al., 2004; Sigman & Ruskin, 1999; Vaughan et al., 2004). Thus, to understand the different pattern of relations of IJA and RJA with social outcomes, it may be important to consider factors beyond caregiver scaffolding. In this regard, it is interesting to consider whether the social-cognitive model enhances our understanding of the processes that may underpin the developmental links between infant joint attention and childhood social competence.

The Social Cognition Model

Recall that part of the foundation for the social-cognitive model emanates from Bruner’s (1975) proposal that, before language acquisition, infants develop the ability to intentionally share information with social partners (i.e.,

communicate) through nonverbal means, such as pointing and showing gestures and eye contact. Bruner and Sherwood (1983) used the term “joint attention” to refer to a subset of these skills and suggested that they reflected a general preverbal cognitive platform that was essential to language development. The notion that preverbal infants *intentionally* share information with others was subsequently elaborated to suggest that joint attention specifically reflects social-cognitive development in infancy (Bretherton, 1991). As previously noted, the logic here is that if infants use gestures and eye contact to intentionally communicate with others, then they must have some awareness not only of the social signal value of their behaviors, but also that others have powers of perception and intention that may be affected by the infant’s behavior. Thus, theory has come to suggest that early prelinguistic communication skills, especially joint attention development, reflects the emergence of social cognition or infants’ “understanding” that others have intentions (Baron-Cohen, 1995; Leslie & Happé, 1989; Tomasello, 1995). Indeed, if one observes 15-month-olds alternating their gaze to share their pleasure in an object, or pointing to show, or pointing to obtain an object (see Figures 9.1c, 9.1b, and 9.1d, respectively), it is difficult to escape the interpretation that these infants are possessed of some degree of understanding that others have emotions and intentions that may be shared and/or directed (Bretherton, 1991).

Of course, the development of social-cognitive awareness is not completed in infancy. Indeed, many researchers suggest that a basic “theory of mind,” or the ability to attribute independent mental states to others, does not mature and become clearly evident until about 4 years of age (Wellman, Cross, & Watson, 2001). This ability may be indexed with performance on a false belief task in which children are asked to predict the behavior of another person based on the child’s understanding of the beliefs of the other person. False beliefs that are not consonant with the perceptual information available to the child are used so the child cannot solve the problem through his or her own knowledge. Instead, the children must think about the other person’s knowledge to solve the problem (see Wellman et al., 2001).

Even after the emergence of this skill in many children by 4 years, significant individual differences have been observed, with some children displaying less understanding of the intentions, feelings, and mental states of others relative to their peers (Astington, 2001; Cutting & Dunn, 2002). Furthermore, critical to the social-cognitive model, several studies now indicate that differences on theory of mind

measures of social cognition in young children is related to both positive (prosocial) and negative (behavior problem) indices of social competence in preschool (Capage & Watson, 2001; Jenkins & Astington, 2000) and school-age (Dunn, 1995; Dunn, Cutting, & Fischer, 2002) children.

Social cognition, though, may also be associated with factors that may inhibit social competence in some contexts. So, for example, Cutting and Dunn (2002) have reported that better-developed social-cognitive skills in 5-year-olds may be associated with enhanced sensitivity to teacher criticism in the 1st year of school. It is also important to recognize that numerous studies suggest that performance on theory of mind measures is significantly correlated with language development (e.g., Peterson, 2004; Ruffman, Slade, Rowlandson, Rumsey, & Garnham, 2003). Therefore, differences in language development may account for part of the relation between social cognition and social competence.

These last two caveats notwithstanding, research and theory on joint attention and social cognition lead to the logical expectation that, (1) if joint attention is an early manifestation of social cognition, and (2) if social cognition is related to later social competence in children, (3) then social cognition may mediate part or all of the relations between social competence and social outcomes observed in recent longitudinal research. This set of assertions rests on the key assumption that infant joint attention behaviors primarily reflect social-cognitive development. Although this assumption has intuitive appeal, the nature of the connection between joint attention and social cognition may be less clear and probably more complex than suggested by the rather simple formulation offered here.

There is surprisingly little direct evidence of a connection between joint attention and social cognition. Indeed, we are aware of only one study that has provided data on this issue. Charman et al. (2000) followed a sample of 13 typically developing infants from 20 to 44 months of age as part of a study on the early identification of Autism. At 20 months, an alternating gaze measure was employed (Figure 9.1c), which involved children spontaneously initiating eye contact with a tester or parent when presented with an interesting toy spectacle. After controlling for differences in IQ and language development, the 20-month IJA alternating gaze measure was a significant predictor of 44-month social-cognitive ability measured on a false belief paradigm.

There are, however, at least two important indirect lines of research that provide data consistent with a connection between infant joint attention and social cognition. One of these involves the observation that children with Autism

display relatively robust disturbances not only in the development of joint attention skills but also in theory of mind task performance. The co-occurrence of these forms of impairment in Autism has suggested that these domains may share a common cognitive foundation (e.g., Leslie & Happé, 1989). Another line of research involves more recent observations from neurophysiological and neuroimaging research (e.g., U. Frith & Frith, 2001; Mundy et al., 2000). This literature indicates that infant joint attention and later performance on theory of mind measures may have common cortical dorsal-medial, orbitofrontal, and temporal cortical activation correlates (Mundy, 2003). Thus, the literature also suggests that joint attention and theory of mind performance share common process foundations. The nature of these common processes, though, is not completely clear at this time and may involve executive as well as social-cognitive processes (see the section on the "Neurodevelopment Executive Model").

Another type of research that is useful in evaluating the connections between joint attention and social cognition involves examining the age of onset of the social-cognitive component of joint attention. Some have argued that true joint attention does not occur until the infant is capable of the simultaneous awareness of self and other contemplating a common object (Tomasello, 1995). This integrated awareness of the perception of self and other is not thought to occur until some time in the 2nd year. However, more recent research and theory suggests that social cognition may only gradually become part of joint attention after several months of practice with social attention (Brooks & Meltzoff, 2002; Moore, 1996). Indeed, the rudiments of joint attention, especially RJA, may emerge between 3 and 6 months of life (D'Entremont et al., 1997; Hood, Willen, & Driver, 1998; Morales et al., 1998; Scaife & Bruner, 1975) and well before theory suggests that social-cognitive processes affect or organize behavior (Mundy & Sigman, 1989; Tomasello, 1995). Indeed, recent empirical efforts indicate that infants display RJA skills in the 1st year of life, but a clear association between this behavior and social cognition does not emerge until the 2nd year of life (Brooks & Meltzoff, 2002; Woodward, 2003).

One way to conceptualize these recent data on joint attention is to think of social cognition as an emergent function that develops, in part, as a consequence of infants' practice with joint attention and joint engagement with others (Mundy & Neal, 2001; Mundy et al., 1993). In this regard, we find it useful to think of joint attention development in terms of two phases: a "learning to" phase and a "learning from" phase (Vaughan & Mundy, *in press*). In the

1st year of development, several basic processes contribute to the capacity of infants to engage in IJA and RJA behaviors. Theoretically, the basic processes that support this “learning to” phase of joint attention development include but are not limited to operant learning (Corkum & Moore, 1998), intersensory integration (Flom & Pick, 2003), motivation for social engagement (Mundy, 1995; Trevarthen & Aitken, 2001), executive attention-regulation processes (Mundy et al., 2000), and imitation (Meltzoff & Moore, 1997; Pomares, Mundy, Vaughan, Block, & Delgado, 2003). With practice, the numerous processes involved in social attention coordination become integrated and routinized, enabling infants to gradually move from the “learning to” phase to the “learning from” phase of joint attention development. In the “learning to” phase of skill acquisition, more neurocognitive resources are utilized than when the skill become routinized (e.g., Wu, Kansaku, & Mark, 2004). Thus, in the “learning from” phase more resources become available to engage in integrative cognitive activities in the context of joint attention interactions with others. That is, practice with the attention management necessary for joint attention combines with neurodevelopmental maturation of cognitive representational and memory resources (Case, 1987) to make it increasingly likely that infants have the capacity to not only engage in joint attention but also process and compare proprioceptive information about their own experience of an object or event with exteroceptive information about their social partners’ experience of the same object or event during a joint attention episode (Mundy et al., 1993).

This comparative process, in the context of social interactions about a common referent, provides the infant with seminal information about the behavioral confluence of self and other that contributes to the development of an awareness that others have thoughts or feelings that are similar to (or different from) the infant’s (Bruner, 1975; Werner & Kaplan, 1963). Indeed, there may be specific neural systems and social executive functions that facilitate self-other information comparison and integration that allows infants to simulate others’ experience based on their own experience, and this simulation gives rise to social cognition (U. Frith & Frith, 2001; Mundy, 2003; Stich & Nichols, 1992; see “Neurodevelopment Executive Model” section for more details). Thus, this theoretical perspective suggests that joint attention may be viewed as a contributing *cause* of social-cognitive development as much as or more than being a *consequence* of social-cognitive development. From this perspective, joint attention may be reasonably viewed as a special form of infant social engagement that contributes to self-constructivist aspects of cognitive

development (Piaget, 1952) that are especially important for subsequent social competence (Mundy, 2003; Mundy & Crowson, 1997; Mundy & Neal, 2001). Theoretically, the constructivist characteristic of the “learning from” phase provides another example of the self-organizing functions of infant joint attention skill development. That is, the more frequently infants engage in episodes of joint attention with others, the more opportunities they have to expand their understanding of similarities and differences in the responses of self and other to external objects and events. It is also very likely that because IJA frequently occurs in the context of sharing positive experiences with others (Mundy et al., 1992), frequent IJA bids may well provide a medium for developing a positive sense of relatedness to others in infancy that has benefits for social development (for discussion, see Mundy & Willoughby, 1996, 1998). The reader may recognize the commonality between this model ascribed to joint attention development and current theory on the importance of imitation for the early development of self-other understanding (Meltzoff & Decety, 2003). Indeed, current research and theory on joint attention and imitation provide important convergent information on social cognition, even though we still know far too little about how these domains relate or interact in development. However, recall that joint attention involves the measures of both self-initiated acts and responsive acts while imitation measures focus on the latter. This is an important distinction. Awareness of one’s own intentional behaviors may provide a foundation that is necessary to perceiving and understanding the intentions of others (Mundy, 2003, 2005) and voluntary self-initiated actions may be critical to the development of representations of intentionality in the self (Lau, Rogers, Haggard, & Passingham, 2004). Hence, self-initiated joint attention acts, in interactions with social partners, may provide a distinct building block of social-cognitive development that is not available through interactions involving imitation or responding to the joint attention behavior of others (Mundy et al., 1993).

The foregoing analysis suggests that the social-cognitive model accounts for some part of the linkage between joint attention and social competence in childhood but does not provide a complete account of the factors that link these domains in development. Other basic processes, more fully described in the next sections on social motivation and neurodevelopment, may need to be considered to understand the connections among joint attention, social cognition, and social competence.

It is also the case that there are empirical observations that do not fit neatly with the current versions of the social-cognitive model. As was the case with the caregiver/scaff-

folding model, we are not aware of a variant of the social-cognitive perspective that makes explicit process differentiations regarding different types of joint attention behaviors. Therefore, the social-cognitive model does not currently provide a ready explanation of why different forms of joint attention behaviors in infancy (IJA, RJA, and IBR) appear to display different patterns of connections with social and behavioral outcomes (Shienkopf et al., 2004; Sigman & Ruskin, 1999; Vaughan et al., 2004). Second, infants in recent longitudinal studies (e.g., Sheinkopf et al., 2004; Vaughan et al., 2004) displayed a range of joint attention skills did not reflect the presence or absence of skill but rather reflected a range of differences from “some” use of joint attention bids to the “frequent” use of joint attention. One challenge for the social-cognitive model is to describe the meaning of this level of individual difference in terms of social-cognitive processes. Third, although joint attention bids may ultimately come to reflect social-cognitive processes, social cognition may not be a primary factor in early joint attention development (Brooks & Meltzoff, 2002; Woodward, 2003). Thus, the social-cognitive model may be less applicable to research on the connections between developmental outcomes and joint attention measured in the early, 3- to 12-month “learning to” phase of development (e.g., Morales et al., 2005; Vaughan et al., 2004). For example, recall that in their study, Vaughan et al. observed that IJA and RJA at 12 months were negatively correlated with parent report of behavior disturbance at 30 months on the Externalizing scale of the ITSEA (Carter & Briggs-Gowan, 2000). The Externalizing domain has 24 items reflecting Defiance (12 items), Activity/Impulsivity (6 items), and Peer Aggression (6 items). In discussing her findings, Vaughan noted that there were few if any items on this scale that appeared to tap social cognition. Hence, there was little content on this scale to suggest that social cognition played a role in the associations between joint attention and this aspect of social outcome in this study. Instead, Vaughan et al. noted that previous research indicated that IJA and RJA had been associated with inhibition and impulse control (Griffith et al., 1999). IJA has also been associated with positive emotional expressivity as early as 9 to 12 months (Mundy et al., 1992; Vaughan et al., 2003) and that RJA at 6 months predicts self-regulatory behavior in a delay of gratification paradigm at 24 months of age (e.g., Morale et al., 2005). Therefore, at least part of the associations of IJA and RJA with the Externalizing that were observed in the Vaughan et al. study may have been carried by these processes. This observation suggests that, in addition to social cognition, it may be important to consider other processes that may con-

tribute to continuity between joint attention and social competence. One essential dimension in this regard may be social-emotional and related motivation process.

The Social Motivation Model

Researchers ask at least two related but distinct questions about the behaviors displayed by infants in Figure 9.1: How are infants able to share attention and experience with others? and Why do infants share attention and experiences with others? The second question leads to reflection on the motivation factors and processes that contribute to the human tendency to share experience with others. For example, consider the following vignette. You attend an event that you are sure you will enjoy (a play, a concert, a sporting event, etc.) and a friend accompanies you to the event. During the event, there is the strong likelihood that several things will happen: (1) You will see/experience something that is rewarding for you, yet (2) you will turn away from the rewarding event (momentarily disengage) to make eye contact with your friend, and (3) in conjunction with the latter, you will experience a sense of relatedness with your friend and possibly a heightened sense of enjoyment regarding the shared experience of the event. In that moment you and your friend are likely engaged in joint attention, much like the infant in Figure 9.1c. Why do we engage in this behavior even when viewing the event by ourselves would be pleasurable? Does the sharing of experience with others hold some positive reward value that motivates people to engage in acts of joint attention throughout the life span? Does this motivation system assist in bootstrapping the development of joint attention and its critical early self-organizing functions in human social development?

Some would respond with an unequivocal yes to the last two questions and go on to suggest that human beings have an innate motivation for sharing experiences or engaging in intersubjectivity. Several groups of developmental scientists have argued that there is an intrinsic preference to orient to social stimuli and faces (Bard, Platzman, Lester, & Suomi, 1992; Valenza, Simion, Cassia, & Umiltà, 1996) and that motivation to engage with caregivers in interactions involving the facial and vocal expression of positive affect contributes an organizing fulcrum around which much of early social and cognitive development revolves (Hobson, 2002; Stern, 1985; Trevarthen, 1979; Trevarthen & Aitken, 2001). With this unfortunately long sentence we have stated a basic tenet of the motivation model.

Recall that between birth and 6 months of age, caregiver-infant dyads increasingly engage in social communication motivation interactions that involve face-to-face

sharing of nonverbal emotional information, or what has been referred to as primary intersubjectivity (Trevvarthen, 1979). Theoretically, the tendency of infants to engage in these interactions is mediated, in part, by an intrinsic neural motivation system. Research suggests that this motivation system may involve temporal, orbitofrontal, and dorsal-frontal brain systems serving the perception of social stimuli (e.g., facial affect), the association of stimuli with positive reward value, and the association of self-initiated social attention behavior with positive rewards (Amador, Schlag-Rey, & Schlag, 2000; Eisenberger, Lieberman, & Williams, *in press*; Mundy, 2003; Trevvarthen & Aitken, 2001; Wantanabe, 1996). Specific neuropeptide-neurotransmitter systems may also be involved that contribute to either a general endogenous reward system involved in learning (Holroyd & Coles, 2002) or a specific system involved in mediating the sensitivity of individuals to the reward value of social stimuli (Panksepp, 1979). Moreover, individual differences in early intrinsic social communication motivation may be associated with a general reward and motivation modulation system that affects the tendency of individuals to display a trait-like tendency to move toward positively rewarding stimuli (behavioral activation) and to avoid threatening or stressful stimuli (behavior inhibition; Gray, 1982). There is some evidence that this behavioral activation and inhibition system is associated with asymmetry in frontal activity (e.g., Sutton & Davidson, 1997) and that the influence of this asymmetric frontal motivation system may be observed in infants in the 1st year of life (Fox & Davidson, 1987, 1988). Some have even suggested that the motivation processes associated with frontal asymmetry may be specifically related to joint attention development and its impairment in Autism (Mundy, 1995).

Other research and theory suggest that, rather than relying solely on an intrinsic biological motivation process, such interactive behaviors as joint attention bids may take on social reward value through processes associated with external operant learning and reinforcement (Corkum & Moore, 1998). Consonant with this, much of the literature on the caregiver/scaffolding model at least implicitly suggests that environmental factors (caregiving) influence children's motivation to engage in social communication and joint attention, at least with selected social partners. Thus, the degree to which the social reward value of interactions reflects intrinsic versus learned processes is a central and as yet unresolved point of debate regarding this model.

In either case, though, a major assumption of this model is that systems of motivation processes serve to organize early behavior and to prioritize social orienting, social in-

teractions, and social information processing in infancy (Dawson, Meltzoff, Osterling, Rinaldi, & Brown, 1998; Mundy & Neal, 2001; Trevvarthen & Aitken, 2001). This prioritization assures a sufficient input of social information to the infant to allow the next step of the development of a more elaborate capacity for sharing of experience with others vis-à-vis some third object, as in secondary intersubjectivity (Trevvarthen & Aitken, 2001) or joint attention (Bruner & Sherwood, 1983; Tomasello, 1995). The strength of this motivation system, though, is likely to vary from individual to individual because of either inherent biological differences in sensitivity to social reward or learned differences in the reward value of social stimuli (Dawson, Munson et al., 2002; Mundy, 1995; Mundy & Willoughby, 1998). The resulting variability in social motivation significantly contributes to differences among infants in the tendency to engage in different types of joint attention skills. A corollary here is the hypothesis that when the motivation to engage in episodes of joint attention and intersubjectivity chronically slips below a critical threshold, because of either endogenous or exogenous processes, the risk for psychopathology increases (Mundy, 1995; Mundy & Willoughby, 1996; Stern, 1985; Trevvarthen & Aitken, 2001).

What sort of empirical verification is there for this model? Well, if joint attention and sharing of experience with others has positive reward value for infants, it may then be reasonable to expect that affect, especially positive affect, should be associated with joint attention development. Indeed, Adamson and Bakeman (1985) have observed that from late in the 1st year through the 2nd year, the exchange of positive affect increasingly becomes a characteristic of infant-caregiver joint attention interactions. Subsequent research has attempted to clarify the degree to which affect is a common component of different types of joint attention skills. Kasari and her colleagues (1990) examined this issue in an investigation of the nature of joint attention deficits in Autism.

Recall that children with Autism displayed more robust deficits in IJA than RJJA or IBR types of behavior. Kasari et al. (1990) hypothesized that the relative severity of IJA deficits may reflect the type of biologically based impairment of affective relatedness to others that Kanner (1943) suggested was a core feature of this disorder. Therefore, to examine the role of affect in autistic joint attention disturbance, Kasari and her colleagues integrated ESCS ratings of joint attention with systematic ratings of facial affect. Several important observations were noted in this study. First, infants in the typical control sample conveyed positive affect significantly more often to social partners in the

context of IJA bids compared to IBR or RJA behaviors. Alternatively, children with Down syndrome and children with Autism did not display differences in affect across IJA and IBR measures, but for different reasons. The Down syndrome children displayed high but equal rates of positive affect across both IJA and IBR bids; the children with Autism displayed low but equal rates of positive affect in IJA and IBR. Infants' expression of positive affect was not a major component of RJA for any group.

These results suggested that the sharing of positive affective experiences with others is a major component of IJA behavior in typical development, and that an attenuation of positive affect in social interactions may be an important component of IJA deficits in children with Autism (Kasari et al., 1990). To examine this issue further, we re-examined the association of affect and joint attention in an independent and larger sample of typically developing infants. This study again revealed that approximately 60% of all IJA bids displayed by toddlers on the ESCS in the 2nd year involved the conveyance of positive affect, but less than 30% of IBR and RJA bids involved the sharing of positive affect (Mundy et al., 1992). These data were interpreted to suggest that IJA in the 2nd year might provide an operational definition of the development of secondary intersubjectivity. That is, IJA, at least as measured on the ESCS, provides a measure that is sensitive to motivation and cognitive factors involved in the tendency of infants to initiate communicative bids to spontaneously share their positive affective experience of object or events with a social partner (see Figure 9.1c).

The argument for a motivation component in IJA rests, in part, on the assumption that some form of internal motivation is necessary to initiate a social behavior to spontaneously convey or share affect in IJA with the social partner. Alternatively, it is possible that the positive affect in IJA is a reactive rather than an intentional sharing of positive affective experience with others. That is, when engaged in triadic attention deployment, infants may smile in response to looking at the face of a social partner rather than as a conveyance of their own preexisting affective state. This type of reactive affective display would be more ambiguous with regard to the possible role of endogenous motivation processes. However, our recent data indicate that, between 8 and 10 months, there is a developmental shift in the association of affect with IJA (Venezia et al., 2004). Prior to 10 months, when typically developing infants engage in an alternating gaze IJA bid (Figure 9.1c), they tend to display affect reactively. That is, they tend to display affect after they look at the face of their social partner. This may be part of "learning to" display af-

fect in IJA development. After 10 months, though, infants tend to smile first at the object or event that has caught their interest and then convey their ongoing affective reaction to an object or event with an IJA bid. One interpretation of these results is that, after about 10 months, many infants begin to display a pattern of behavior that is consistent with the possibility that they are motivated and intend to initiate sharing affect with others as part of an IJA bid (Venezia et al., 2004).

The current state of the argument for the role of motivation in joint attention development may be conjectural, but it also has considerable face validity (see Figure 9.1c). This unintended pun notwithstanding, the data on the facial emotional component of IJA are at least consistent with the hypothesis that this type of joint attention behavior may reflect a prosocial motivation to share affective experience with others. Of course, if this is true, then joint attention, or at least IJA development, may be related to aspects of temperament, such as emotional reactivity. Data from two recent studies are consistent with this possibility. Vaughan et al. (2003) observed that 9-month infant-tester IJA on the ESCS was significantly related to parent reports of "low pleasure" or a heightened tendency to express positive affect on the Infant Behavior Questionnaire (Rothbart, 1981). Parents' ratings of fearful responsiveness to novelty was later associated with IJA at 12 months. Neither IBR nor RJA displayed significant relations with indices of emotional reactivity (Vaughan et al., 2003).

Thus, current research suggests that some forms of joint attention, such as IJA, may reflect the tendency of infants to engage others in the spontaneous sharing of affective experience of objects or events. Alternatively, other measures of joint attention, such as RJA, do not as clearly involve affective sharing. This distinction may contribute to the different and unique paths of association observed between RJA, IJA, and social outcomes in children (Sheinkopf et al., 2004; Vaughan et al., 2004). However, as noted earlier, still other processes (e.g., self-regulatory processes) may also be involved in the connections between measures of infant joint attention skills and social competence. The breadth and nature of these additional processes are beginning to be revealed in research on the neurodevelopmental executive model of joint attention.

The Neurodevelopment Executive Model

The emergence of the neurodevelopmental executive model of joint attention has been stimulated in no small part by the need to better understand the nature of joint attention disturbance in Autism. It was previously noted that Autism

is a biologically based disorder (Dawson et al., 2001) and that a cardinal symptom of this syndrome is a robust early disturbance of joint attention development (Mundy & Sigman, 1989; Mundy et al., 1986). Remember, however, that with development, there is evidence of dissociation in the course of joint attention impairments. In the 1st years of life, children with Autism display a clear deficit in RJA skills. Nevertheless, they begin to display basic gaze following by 2 years of age (Charwarska, Klin, & Volkmar, 2003), and problems in RJA appear to remit to an adaptively significant degree among many older children with Autism and those with higher mental ages (Leekam et al., 2000; Mundy et al., 1994; Sigman & Ruskin, 1999). Alternatively, IJA-related deficits appear to remain a profound source of disturbance throughout childhood with Autism (Leslie & Happé, 1989; Lord et al., 2001; Mundy et al., 1994; Sigman & Ruskin, 1999), although some children with Autism display improvement even in this area (Kasari, Freeman, & Paparella, 2001).

This literature on joint attention disturbances in Autism has numerous implications. First, examining the neural substrates of an early emerging cardinal symptom, such as joint attention impairment, may be essential to understanding the neurodevelopmental etiology of this disorder. Second, the research on dissociation in the development of IJA and RJA impairments in Autism suggests that it is possible that these two forms of joint attention reflect different constellations of neurodevelopmental processes. Numerous studies have now been reported that bear on this possibility.

Caplan and colleagues (1993) provided what may have been the first data on this issue. This research team studied the behavioral outcome of 13 infants who underwent hemispherectomies in an attempt to treat their intractable seizure disorders. The ESCS was used to assess the post-surgical development of joint attention and related behaviors among these children. Positron emission tomography (PET) data were gathered prior to surgical intervention. PET data indicated that metabolic activity in the dorsal-frontal cortex, especially the left frontal cortex, predicted the development of IJA skill in this sample. However, the PET data did not predict the development of the capacity to respond to the joint attention bids or to initiate requesting bids. Moreover, metabolic activity recorded from other brain regions (e.g., ventral-orbitofrontal, temporal, parietal, and occipital cortices) was not significantly associated with the development of joint attention or other social communication skills in this study. Thus, dorsal-frontal activity appeared to be specifically related to the development of the tendency to spontaneously initiate social attention coordination with others to share experience.

A post hoc explanation of this frontal connection to IJA was offered in a later paper based on the social motivation model (Mundy, 1995). By about 10 months of age, a frontal and left-lateralized system emerges that plays a role in the executive and emotional processes associated with approach tendencies involved in positive social affiliative behaviors (e.g., Fox, 1991). Mundy suggested that IJA impairment in Autism might reflect a disturbance in the emergence of this left frontal social-approach system. Based on earlier work (Panksepp, 1979), the specific hypothesis was that pathology in Autism involved the early onset of a disturbance in frontal neurotransmitter mediated sensitivity to the reward value of social stimuli. This attenuated social reward sensitivity hypothetically creates an affective social motivation imbalance that results in a robust decrease in the tendency to direct attention to social stimuli. This, in turn, leads to a dramatic reduction in the tendency of infants with Autism to initiate joint attention bids and a related reduction in social information input to the child that results in a marginalization of subsequent social-cognitive and social-behavior development (Dawson et al., 1998; Mundy, 1995; Mundy & Crowson, 1997; Mundy & Neal, 2001).

To begin to test aspects of this model, a study was conducted at the University of Maryland in collaboration with the research team of Nathan Fox (Mundy et al., 2000). This study examined the hypothesis that EEG activity in a left-lateralized, frontal-cortical system would be a significant correlate of IJA among infants with typical development. Baseline EEG and ESCS joint attention data were collected on 32 infants at 14 to 18 months of age. The results indicated that individual differences in 18-month IJA were predicted by a complex pattern of 14-month EEG activity in the 4Hz to 6Hz band that included indices of left medial-frontal EEG activation, as well as indices of right central deactivation, left occipital activation, and right occipital deactivation. Although the location of the generators of the EEG data could not be definitively determined in this study, the frontal correlates of IJA reflected activity from electrodes at F3 and C3 of the 10/20-placement system (Jasper, 1958). These electrodes were positioned above a point of confluence of Brodmann's areas 6, 8, and 9 of the medial-frontal cortex of the left hemisphere (Martin, 1996). This area includes aspects of the frontal eye fields and supplementary motor cortex, commonly observed to be involved in attention control (Posner & Petersen, 1990). Moreover, theory on the anterior attention network (Posner & Petersen, 1990) suggested that, in addition to medial frontal cortical activity, data from these electrodes may have reflected activity in the anterior cingulate (Brodmann's area 24), a sub-

cortical structure contiguous with the ventral surface of Brodmann's cortical areas 6, 8, 9 (Martin, 1996). Alternatively, neither RJA nor IBR measures were associated with a similar pattern of EEG activity (Mundy et al., 2000). However, RJA at 18 months was predicted by EEG indices of left parietal activation and right parietal deactivation at 14 months.

These data suggested that at least two neural systems might be involved in joint attention development: a temporal and parietal system for RJA and a dorsal-medial cortical system for IJA. Other research provides support for this dual process model and also offers hypotheses about the nature of the process that may be involved in these two systems (for recent reviews, see Mundy, 2003; Vaughan & Mundy, *in press*). This additional research is reviewed in the next sections, beginning with information on the connections between RJA-related behaviors and parietal and temporal systems.

RESPONDING TO JOINT ATTENTION AND THE PARIETAL-TEMPORAL PROCESS

RJA is a complex behavior. On the ESCS, it involves the ability of the child to attend to and process information provided by another person and then to disengage attention as well as reorient to correctly follow the direction of gaze, head and body posture, and pointing gesture of a social partner. Much of the work related to RJA focuses on mapping the cortical systems that are engaged in processing the direction of gaze of a social partner.

Wicker, Michel, Henaff, and Decety (2002) observed that neural groups in the posterior superior temporal sulcus (STS) were activated in response to faces with direct or horizontally averted eye gaze, but not to faces with downward eye gaze. However, Wicker et al. did not observe differences between direct and averted eye gaze conditions. Alternatively, Puce, Allison, Bentin, Gore, and McCarthy (1998) reported that videos of face stimuli with gaze moving horizontally from forward to averted gaze elicited greater posterior STS activation compared to faces with static forward gaze. Face matching on the basis of direction of gaze also elicited activation of neurons in the left posterior STS, and identity-based face matching elicited bilateral activation from the fusiform and inferior occipital gyri (Hoffman & Haxby, 2000). Similarly, George, Driver, and Dolan (2001) reported that direct gaze stimuli elicited more fusiform activation than averted gaze stimuli. Kingstone, Friesen, and Gazzaniga (2000) have also reported data on gaze following in two split-brain patients that was

consistent with the notion that parietal as well as temporal subsystems specialized for face processing and processing of information relevant to spatial orientation combine to support the development of gaze following. Finally, Hooker (2002) used whole-brain fMRI to compare neural activity in response to (1) horizontal eye movement stimuli that provide directional information about where a visual stimulus would appear, or (2) arrow stimuli that provided equivalent directional information, or (3) eye movements that did not provide directional information. Hooker observed more activity in the STS in the first condition compared to either of the other conditions. Alternatively, Hooker reported more activity in the fusiform gyrus and prefrontal cortex in the eye motion control condition (condition 3) compared to the other conditions. Similarly, Kingstone, Tipper, Ristic, and Ngan (2004) also compared the response of shifts in attention elicited by direction of gaze (eye stimuli) versus a direction indicator (arrow stimuli) and observed that the neural systems that subserved the respective orienting were not equivalent. The STS was clearly engaged when the stimuli were eyes versus arrows. These data are consistent with the notion that the STS may develop a specialization for processing gaze-related, social-spatial orientation information.

The results of these human imaging studies are consistent with earlier reports from comparative research that provide experimental evidence of temporal (i.e., STS) and parietal involvement in gaze following (Emery, 2000). In two studies, presurgical monkeys demonstrated a clear ability to discriminate face stimuli on the basis of direction of gaze (Cambell, Heywood, Cowey, Regard, & Landis, 1990; Heyward & Cowey, 1992). After resection of the STS, however, the gaze discrimination abilities of the monkeys fell to chance. Eacott, Heywood, Gross, and Cowey (1993) compared two groups of monkeys, those with and without STS surgically induced lesions, on a task requiring discriminating between pairs of eyes directed straight ahead or averted 5 or more degrees. The results indicated that the nonlesion monkeys were capable of discriminating targets involving horizontal eye gaze shifts of greater than 5 degrees, but the STS lesion animals were not.

Few studies, though, have reported a significant connection between RJA or gaze following and activity in the frontal cortices. Calder et al. (2002) suggested that perhaps task difficulty needed to be considered in this regard. Most studies have examined passive gaze following on tasks that did not require the perception or inference of intentions on the basis of eye gaze. These authors suggested that more complex presentations of sequences of gaze stimuli may elicit inferential social-cognitive processing

and evidence of more dorsal contributions to the neural substrate of gaze following. To this end, Calder et al. used PET to examine the neural responses of 9 female volunteers to a relatively complex sequence of faces with gaze averted left or right, gaze direct, and gaze down orientations. Hypothetically, this procedure elicited interpretation of the nature of meaning of the gaze direction (i.e., the intentionality of gaze direction). In this paradigm, evidence of activation in the dorsal-medial-frontal cortex (BA 8, 9), the anterior cingulate (BA 32), and the STS was observed in response to horizontal gaze aversion. This study, unlike most others, employed a sample of women rather than men. Therefore, it is unclear whether an unrecognized gender effect may have also played a role in these observations. Nevertheless, the degree to which research participants attempt to process the “meaning” of gaze rather than simply direction of gaze may elicit a frontal component associated with RJAs-related behaviors.

Another line of connection to the STS-parietal systems has been described by Meltzoff and Decety (2003). These authors provided an important research review that indicates neural activity associated with imitation clusters in the STS and parietal lobes, as well as the dorsal-cortical supplementary motor areas (BA 8, 9). In particular, they note that there may be an abundance of “mirror” neurons in STS and parietal lobes. Mirror neurons are motor neurons that activate both when an individual performs a particular action and when an individual observes the same action performed by another person (Rizzolatti & Arbib, 1998). These neurons may be integral to imitation. Thus, the proposed location of some of the neural mediators of imitation may overlap with the systems that are thought to mediate the development of gaze following and RJAs. Indeed, from a task analytic point of view, this makes a great deal of sense. Gaze following and RJAs basically involve copying the eye movements and/or head turns of a social partner. Indeed, RJAs development has been observed to display a significant path of association with imitation development in a longitudinal study of typically developing infants (Pomares et al., 2003). However, there were no observations of significant associations between the development of IJA and imitation. This is not too surprising, as IJA behaviors are self-generated and do not appear to involve a discernable social copying component. Thus, it may be useful in future research to better understand the degree to which imitation and gaze following/RJAs, but perhaps not IJA, reflect common biobehavioral processes in early development. Indeed, the importance of this issue has long been recognized in research on Autism because this syndrome

involves deficits in imitation as well as joint attention skill development (e.g., Rogers & Pennington, 1991).

In addition to the specifically social information-processing functions of the STS and parietal cortices, this system also mediates more general, basic attention functions. For example, this system is also associated with the posterior attention network, which by 2 to 4 months of age contributes to the capacity to disengage from a focal central stimulus and reorient to a new aspect of the environment (Posner & Dehaene, 1994; Rothbart et al., 1994). The capacity to disengage may also be fundamental to RJAs-related behaviors (Mundy et al., 2000). This is because, in their development, infants must learn to disengage from a preferred social stimulus (e.g., face of caregiver) to follow gaze and reorient to some new, shared focus of attention (see Figure 9.1). It is important to recognize the potential contribution of this basic function of the posterior attention system to the development of RJAs for two reasons. One reason has been outlined by the recent work of R. Landry and Bryson (2004) that reports that 3- to 7-year-old children with Autism are impaired in their ability to disengage visual attention from an attractive central stimulus in order to reorient to peripheral targets. R. Landry and Bryson suggest that this type of impairment may contribute to social disturbances in Autism. We would agree and further suggest that it will be important to determine empirically if disengagement impairment as measured on a nonsocial task, such as described by R. Landry and Bryson, is related to the disturbances of joint attention development in Autism. Equally important will be to determine if variance associated with a nonsocial disengagement task fully explains or mediates the relation observed between RJAs and outcomes in Autism such as intervention responsiveness (e.g., Bono et al., in press). Our guess is that nonsocial disengagement tasks will help us to understand some of the components of the processing impairment intrinsic to joint disturbance in Autism. However, because joint attention measurement is specific to the expression of attention management in social interactions, and social attention management likely involves many component processes not indexed by nonsocial attention measures, it seems unlikely that nonsocial measures will fully explain the significance of joint attention impairment in Autism. This, of course, is merely an opinion that we hope will either be corrected or supported by future research.

Another reason that understanding the role of disengagement in RJAs may be important relates to the role of attention management in self-regulation. Rothbart et al. (1994) suggested that the capacity to disengage attention

from a stimulus might be critical to the developing capacity of infants to modulate arousal in interactions with people and objects. For example, infants may disengage and briefly turn away from caregivers to modulate negative or positive affective arousal that occurs in response to processing information in social interactions. Thus, attention management may contribute to self-regulation processes that enable children to participate in social interaction more adaptively and for longer periods of time (Rothbart et al., 1994). This link between disengagement and self-regulation may help to explain part of the connection between RJA and the subsequent development of social competencies. For example, Morales et al. (2005) recently reported that RJA measured in the context of infant-caregiver interactions at 6 months predicts the tendency of toddlers to use disengagement strategies to self-regulate in a delay of gratification paradigm. Infants with better RJA skills at 6 months tended to look away from the desired object more frequently in the delay of gratification task. Thus, theory and research on disengagement of attention may assist us to better understand the RJA impairments in Autism as well as the connections between infant RJA and social outcomes. Much more work is needed on this intriguing possibility.

INITIATING JOINT ATTENTION AND FRONTAL PROCESSES

The study of the neural correlates of social initiations like IJA is a bit more difficult than the study of responsive behaviors such as RJA. This is because it is more complicated to establish a paradigm that is compelling enough to encourage children to spontaneously initiate valid social bids while also allowing for sufficient experimental control to gather imaging or electrophysiological data. Therefore, relatively few studies have been conducted on the neural correlates of IJA or its analogues. Previously, we noted that Caplan et al. (1993) and Mundy et al. (2000) provided PET and EEG data, respectively, that suggested that IJA may be related to frontal activity, specifically left dorsal-medial-frontal activity (Brodmann's areas 6, 8, 9). A more recent EEG study conducted by Henderson et al. (2002) has provided a seminal replication and extension of these earlier observations.

Henderson et al. (2002) used the ESCS in a study of the degree to which baseline EEG at 14 months predicted 18-month joint attention development in 27 typically developing infants. However, compared to Mundy et al. (2000), they

used a higher-density array of 64 electrodes to improve the spatial resolution of their data. Moreover, because the total ESCS scores for measures of IJA and other domains used in Mundy et al. were composites of several behaviors, the Henderson team reasoned that the exact nature of the associations with EEG activity were unclear in that earlier study. Therefore, Henderson et al. compared the EEG correlates of only two types of behaviors: self-initiated pointing to share attention with respect to an active mechanical toy (IJA pointing) and self-initiated pointing to elicit aid in obtaining an out-of-reach object (IBR pointing). In the ESCS, the former involves pointing to an active mechanical toy that is within easy reach, and the latter involves pointing to an inactive toy that is out of reach.

Henderson et al. (2002) found no significant correlations between any of the 14-month EEG data and IBR pointing at 18 months. However, in the 3Hz to 6Hz band, IJA pointing at 18 months was significantly predicted by 14-month EEG data, indicative of greater brain activity over the medial frontal cortex. These correlations involved electrodes that were placed above cortical regions corresponding to Brodmann's areas 6, 8, and 9. Henderson et al. also analyzed data from the 6Hz to 9Hz bands, which revealed 15 significant correlations between 14-month EEG data and 18-month IJA pointing. Again, higher bilateral activity corresponding to the previously identified medial-frontal sites was a strong predictor of IJA pointing at 18 months. In addition, though, IJA pointing at 18 months was also predicted by activity in this bandwidth from the orbitofrontal, temporal, and dorsolateral-frontal cortical regions.

The bilateral nature of the Henderson et al. (2002) findings suggested that Mundy's (1995) social motivation model's focus on only left frontal contributions to IJA processes may, at best, be incomplete. Indeed, these bilateral data are consistent with data from Vaughan et al. (2003) that suggest that IJA may be associated not only with positive affect and motivation tendencies associated with relative left frontal activation but also with negative affect and motivation tendencies that have been associated with relative right frontal activation. Nevertheless, the Henderson et al. study again indicated that IJA development might reflect dorsal-frontal cortical functions (Mundy et al., 2000). However, it also suggested that IJA might be affected by a broader cortical system that also may involve ventral "social brain" and dorsolateral functions that have been identified as contributing to IJA in other studies (Dawson, Munson, et al., 2002; Griffith et al., 1999). There was, however, little evidence for parietal involvement in IJA in this study.

The study of Henderson et al. (2002) also provided information about the social specificity of the link between IJA and dorsal-cortical brain activity. Remember that the specific dorsal-medial-frontal cortical areas involved in IJA corresponded to aspects of both the frontal eye fields and supplementary motor cortex associated with the control of saccadic eye movement and motor planning (BA 6, 8; Martin, 1996). Therefore, these associations could simply reflect the motor control of the eye movements and/or gestural behaviors that are intrinsic to joint attention behaviors. However, the simple elegance of the Henderson et al. study controls for this possible interpretation. The gross motor topography of IJA pointing and IBR pointing is virtually identical on the ESCS. Therefore, a neuro-motor explanation of the different cortical correlates of IJA and IBR appears unlikely. Instead, because IJA pointing and IBR pointing appear to serve different social communicative functions, it is reasonable to assume that the difference in EEG correlates of these infant behaviors also reflects differences in the neurodevelopmental substrates of these social communicative functions.

The data from Henderson et al. (2002) suggest that IJA behaviors reflect a complex system of brain activity that includes not only the dorsal-medial cortex but also activity associated with the dorsolateral, orbitofrontal, and temporal cortex. Several neuropsychological studies have provided data consistent with this more complex systems view of IJA. In a study of the possible functions that contribute to joint attention deficits in Autism, IJA as well as RJA performance was observed to be associated with a spatial reversal task, which comparative research indicates involves dorsolateral mediation of response inhibition, planning, and memory (Griffith et al., 1999; McEvoy et al., 1993). Spatial reversal tasks involve searching for hidden objects and flexibly inhibiting reach and altering search strategies throughout the task. Hence, these data suggest that frontal mediation of inhibitory planning and memory may not necessarily be a specific component of IJA but may be a general frontal component of both types of joint attention skills. However, although they displayed joint attention deficits, the children with Autism in this study did not display deficits on the spatial reversal task. Thus, these results suggested that functions associated with spatial reversal impairment were related to joint attention development but not so clearly related to joint attention impairments in Autism.

Another important neuropsychological study has been provided by Dawson, Munson, et al. (2002), who examined the degree to which joint attention in Autism was correlated with neuropsychological measures associated with an

orbitofrontal brain system, rather than a dorsolateral-frontal system. This study was based on the hypothesis that an IJA disturbance in Autism involves an impairment of the reward sensitivity that is mediated by an orbitofrontal and temporal circuit (Dawson, Munson, et al., 2002). To assess this dimension, the authors presented children with a delay-not match to sample task (DNMS). This is another type of object search task, but it is designed, in part, to measure children's sensitivity to reinforcement. Specifically, it measures the capacity of the child to adopt a search strategy that involves ignoring a visual sign that has previously been associated with finding the hidden object (e.g., an "M&M's" reward) in order to look in a hiding place associated with a novel sign. Performance on this task has previously been associated with orbitofrontal activity in comparative research. For comparative purposes, Dawson, Munson, et al. also presented children with an A-not-B reversal task previously associated with dorsolateral activity. The results indicated that joint attention in both children with Autism and typical controls was associated with the DNMS task, but not the A-not-B task. Thus, consistent with findings from Henderson et al. (2002), this study provided evidence of a more ventral-frontal contribution to joint attention. Dawson, Munson, et al., however, used a composite measure of IJA and RJA in their study. Therefore, it was difficult to determine if this more ventral component was associated specifically with IJA.

This issue has been addressed in a new study by Nichols et al. (2005). They worked with 39 typically developing infants and examined the relations of DNMS task performance with measures of IJA and RJA in the 14- to 18-month period. However, because previous research had implicated the contribution of the dorsal-medial cortex to IJA, the authors also examined data from a behavioral task that hypothetically may be related to activity in this brain region. The dorsal-medial cortex appears to play a fundamental role in self-monitoring and self-awareness (Buch, Luu, & Posner, 2000; Craik et al., 1999; C. Frith & Frith, 1999; U. Frith & Frith, 2001; Johnson et al., 2002; Stuphorn, Taylor, & Schall, 2000). For example, recent research indicates that the dorsal-medial-frontal cortex plays a role in encoding and recalling words and actions that involve self-reference awareness, but not necessarily those that do not involve self-reference (Craik et al., 1999; Johnson et al., 2002). Nichols et al. used a measure of infant self-recognition as a means for accessing this domain of behavior. They hypothesized that if the data from Henderson et al. (2002) were correct, then it was likely that variance in both an orbital-frontal-related behavior (DNMS) and a putative dorsal-medial-related

behavior (self-recognition) would make unique contributions to the explanation of variance in IJA development.

Consistent with this hypothesis, both task performance on the DNMS and the self-recognition measures made significant contributions to a multiple regression for 18-month IJA. However, these measures did not contribute to the explanation of 18-month RJA data. Hence, consistent with the findings of Henderson et al. (2002), the data indicated that measures associated with both orbitofrontal and dorsal-medial-frontal systems were related to IJA development. The contribution of these systems to RJA is less clear. The integrated functioning of these two brain systems may be critical not only for IJA development, but for later-developing aspects of social engagement and social competence as well. A better appreciation of how these systems, especially the dorsal-medial-frontal system, may contribute to social competence may be gleaned from the recent literature on the anterior attention system (Posner & Petersen, 1990; Rothbart et al., 1994).

ON THE NATURE OF DORSAL-MEDIAL CORTICAL FUNCTIONS

The anterior attention system is associated with functions of the dorsal-medial-frontal cortex (BA 8, 9) and the anterior cingulate (BA 24). This anterior network may become more active after the posterior parietal system and is thought to make numerous contributions to the planning, self-initiation, and self-monitoring of goal-directed behaviors, including visual orienting (Rothbart et al., 1994). One important process here is the anterior attention system's contribution to the capacity to share attention across dual tasks or foci of attention (Birrell & Brown, 2000; Rushworth, Hadland, Paus, & Siplia, 2002; Stuss, Shallice, Alexander, & Picton, 1995). Thus, the anterior attention system may play a role in infants' ability to maintain representations of self, a social partner, and an interesting object spectacle, while flexibly switching attention among these foci in IJA behaviors (Mundy et al., 2000; see Figure 9.1, c1–c3). This attention-switching facility of the anterior system plays a critical role in the supervisory attention system (SAS; Norman & Shallice, 1986), which functions to guide attention deployment and behavior, *depending on the motivational context of the task* (e.g., Amador et al., 2000; Buch et al., 2000).

Ultimately, the anterior system comes to participate in monitoring and representing the self, as well as switching attention between internal proprioceptive (self-information) and exteroceptive information about external events (Faw, 2003). For example, two research groups have reported that

self-referenced memory processes preferentially activate the dorsal-medial-frontal cortical component of this anterior system (Craig et al., 1999; Johnson et al., 2002). Other research on self-monitoring indicates that, in EEG studies, when people make an erroneous saccadic response in an attention deployment task, there is a negative deflection in the stimulus and response-locked event-related potentials (ERP), called the error-related negativity, or ERN (Buch et al., 2000; Luu, Flaisch, & Tucker, 2000). Source location suggests that the ERN emanates from an area of the dorsal-medial-frontal cortex (DMFC) proximal to the anterior cingulate (AC) cortex (Luu et al., 2000). Observations of the ERN suggest that not only are there specific cell groups within the DMFC/AC that are active in initiating a behavioral act, such as orienting to a stimulus, but there are also distinct cell groups involved in processing the positive or negative outcome of the response behavior (i.e., accuracy and reward information; Amador et al., 2000; Holroyd & Coles, 2002). Thus, like the orbitofrontal cortex, the dorsal-medial-frontal cortex appears to play a role in the appraisal of the valence of stimuli, in the generation or modulation of emotional responses to stimuli, and in mediating the subjective experience of emotion and reward in social behavior (e.g., Hornak et al., 2003; Lane, Fink, Chua, & Dolan, 1997; Ochsner, Bunge, Gross, & Gabireli, 2002; Teasdale et al., 1999). Indeed, specific lesions of the orbital-frontal cortex or dorsal-medial-frontal cortex (BA 9 and anterior cingulate) appear to be associated with deficits in voice and face expression recognition, social behavior, and appraisal of subjective emotional states (Hornak et al., 2003).

Finally, with respect to directing attention to external and internal events, Frith and Frith (C. Frith & Frith, 1999; U. Frith & Frith, 2001) have argued that the DMFC/AC integrates proprioceptive self-information (e.g., emotions or intentions) with exteroceptive perceptions processed by the STS about the goal-directed behaviors and emotions of others. This integrative activity may be facilitated by the abundance of connections between the DMFC/AC and the STS (Morecraft, Guela, & Mesulam, 1993). Indeed, cell groups in and around BA 8, 9 may be especially well connected to the STS (Ban, Shiwa, & Kawamura, 1991). We have described this putative facility for integrating proprioceptive self-information with exteroceptive social perceptions as a social executive function (SEF) of the dorsal-medial-frontal cortex and anterior cingulate system (Mundy, 2003). Hypothetically, this SEF utilizes the DMFC/AC facility to split attention among multiple representations in working memory to compare and integrate the actions of self and others. This integration gives rise to the

capacity to infer the intentions of others by matching them with representations of self-initiated actions or intentions (Stich & Nichols, 1992) and recent research suggests that the representation of self-intention is mediated by circuits within the DMFC that include the supplementary motor cortex (Lau et al., 2003). Once this integration begins to occur in the DMFC/AC, a fully functional, adaptive human social-cognitive system emerges with experience (C. Frith & Frith, 1999; U. Frith & Frith, 2001). Indeed, there is considerable evidence that DMFC/AC activity is associated with attributing intentionality and performance on theory of mind measures in adults (Brunet, Sarfati, Hardy-Bayle, & Decety, 2000; Castelli, Happé, Frith, & Frith, 2000; Fletcher et al., 1995; Gallagher et al., 2000; Goel, Grafman, Sadato, & Hallett, 1995; Schultz, Romanski, & Tsatsanis, 2000). Of course, this version of the neurodevelopment model asserts that the social-cognitive facility is an emergent property of the DMFC/AC system. That is, earlier DMFC/AC behaviors, such as joint attention, contribute to the emergence of social cognition as much as or to a greater degree than social cognition contributes to the development of joint attention.

CONCLUSIONS AND FUTURE DIRECTIONS: JOINT ATTENTION AND RESEARCH ON ATTENTION-DEFICIT/HYPERACTIVITY DISORDER AND MALTREATMENT

The literature and ideas discussed in this chapter have revolved around several main themes. First, the study of joint attention does not fall only within the purview of those interested in language development or social cognition, but also has relevance for those interested in more general aspects of social competence associated with the development of social motivation, self-regulation, and executive processes. Second, research is beginning to suggest that observation of joint attention skills may provide unique information about early *social* neuropsychological processes that contribute to the development of social competence (e.g., social executive attention management, self-other monitoring). Third, joint attention may be a vehicle or platform for social constructivist process in early development. Finally, joint attention provides an operationalization and means of measuring individual differences in the tendency of young children to engage in episodes of intersubjectivity with others. Intersubjective process is a pivotal component of several theories of early interpersonal development and the pathological sequelae of disturbances in this domain

(e.g., Fonagy, 2003; Stern, 1985; Tronick, 1998). Therefore, developmental and neuropsychological theory suggests that, beyond its prominent application in research on Autism, measures of joint attention skill development in young children may have important applications to broader aspects of theory and research in developmental psychopathology. An important future direction for research on joint attention is to examine these potential applications.

To support these assertions, we have reviewed a recent set of longitudinal studies that provide evidence of significant predictive associations between individual differences in infant joint attention skill development and observations of social competence and behavior disturbance in toddlers and children. We have also suggested that no one model currently provides a full and veridical explanation of the links between joint attention and competent versus impaired social development in childhood. Rather, joint attention is a complex and fundamental skill. Individual differences in development within this domain are affected by differences in caregiving, but also reflect variability in the neurodevelopment of executive, motivation, and social-cognitive functions. Indeed, joint attention skill development may be considered a nexus around which much of early social neurobehavioral development revolves (Mundy, 1995).

Of course, the question comes to mind, If joint attention is such an important “nexus” in early development, why hasn’t it become a more prominent focus for research on early processes involved in developmental psychopathology? Historically, there may have been several issues and misconstruals concerning joint attention that have held back research and theory development in this regard. For example, for some, the identification and examination of age-related changes in the emergence of different types of skills is the primary goal of developmental research on joint attention. Clearly, this is an essential goal of developmental research. Nevertheless, the focus on age-related change might have obfuscated an equally important developmental phenomenon. Children in all age and developmental groups (i.e., typical or atypical) that we have examined display significant individual differences in the development of joint attention skills. Why do such striking differences in the development of such a fundamental social skill domain arise, and what meaning do they have for the social outcomes of children?

The resolution of these questions constitutes another essential goal of basic and applied research on joint attention development. The task of addressing this goal has recently been facilitated by the observation that individual differ-

ences in infant joint attention development may be reliably and validly assessed beginning at about 6 months of age and with increasing precision through 18 to 36 months of age (e.g., Adamson, Bakeman, & Deckner, 2004; Mundy et al., 2000; Sheinkopf et al., 2004). Indeed, thanks in part to research on Autism, numerous video-based observational methods have now been developed to assess joint attention and related social communication competencies in young children (e.g., Adamson et al., 2004; Lord et al., 1999; Mundy et al., 2003; Stone et al., 2000; Wetherby, Allen, Cleary, Kublin, & Goldstein, 2002). Moreover, to increase the efficiency of these measures, research groups have developed parent report measures of joint attention and related skills (Baron-Cohen et al., 1996; Robins, Fein, Barton, & Green, 2001; Wetherby et al., 2002) as well as live scoring systems for some of the structured observation-based research instruments (Thorp & Mundy, 2004). Hence, a wealth of measures now exist that may be put to better use in understanding the role of individual differences in joint attention skill acquisition in typical and atypical social-emotional development. Indeed, a useful goal of one component of future research in this arena will be to determine if a combination of extant measures, such as parent report and live observation methods, may provide greater precision, reliability, and validity in the assessment of this fundamental domain of development.

Research on joint attention and social competence may have also been hampered by the misconception that the study of joint attention is applicable only to the more extreme forms of social developmental psychopathology, such as Autism. To be sure, research on joint attention has been instrumental in opening new perspectives on the neurobehavioral development, diagnosis, and treatment of children with Autism (e.g., Kasari et al., 2001; Mundy, 2003; Mundy & Crowson, 1997; Mundy & Sigman, 1989; Whalen & Schreibman, 2003). The observation that joint attention impairment is associated with the deep-seated social and behavioral impairments of Autism, however, also gives reason to suspect that lesser impairments of joint attention skills may play a role in other aspects of developmental psychopathology. We hope this chapter has provided the reader with a more detailed appreciation of this possibility. For example, the content and emerging neuropsychological validity of joint attention measures suggest that they provide a unique paradigm for the assessment of social attention management abilities in young children. As such, it is plausible to suggest that the measurement of joint attention skills may be instrumental in the early identification of children at risk for attention-related disorders and associ-

ated externalizing behavior disturbance (e.g., ADHD). Indeed, the recent observations that better joint attention development at 18 months was negatively associated with first grade parent and teacher ratings of hyperactivity and attention problems in children with in utero cocaine exposure provide intriguing support for this hypothesis (Acra et al., 2003). One potentially significant area of future research may be to follow up on the distinct possibility that joint attention reflects individual differences in the development of social attention regulation that ultimately are related to the expression of childhood ADHD and related externalizing forms of developmental psychopathology.

Another issue that may have hampered the realization of the utility of joint attention measures in developmental psychopathology is the confusion regarding the nature of the overlap of joint attention with other domains of inquiry. For example, after reading the section on the social motivation model in this chapter, it may be reasonable to suggest that, in some sense, "joint attention is just another term for intersubjectivity." This is true in part, and recognizing the connections between joint attention and intersubjectivity may be of some benefit to the science of developmental psychopathology.

Theory on intersubjectivity plays a major role in several contemporary formulations of developmental psychopathology. To translate this theory to research, though, requires operational measures with adequate psychometric properties. Although some relevant measures exist, research on intersubjective processes in developmental psychopathology could undoubtedly benefit from additional empirical paradigms and perspectives. Joint attention assessments provide one additional paradigm in this regard that offers highly reliable infant/toddler measures of the tendency to engage in intersubjectivity with either caregivers or unfamiliar social partners. We have tried to emphasize here, and elsewhere (e.g., Mundy et al., 1992; Mundy & Hogan, 1994), that these measures provide a useful means of examining theory about how impairments in the capacity for intersubjectivity in young children may develop and how these may relate to subsequent typical or atypical social-emotional development.

To reiterate the logic of this proposition, we believe that (1) if measures of joint attention, especially measures of IJA, provide a meaningful index of the tendency of infants to engage in positive episodes of intersubjectivity with others (e.g., Mundy et al., 1992; Mundy & Hogan, 1994); and (2) the capacity to engage in positive episodes of intersubjectivity may be a critical aspect of self- and social-emotional development that ultimately affects the ability

of children to establish an adaptive level of relatedness with peers, teachers, and other caregivers (e.g., Cicchetti & Toth, 1995; Stern, 1985; Trevarthen & Aitken, 2001; Tronick, 1998); then (3) infant and toddler measures of joint attention may be useful in developmental psychopathological research on early risk and resilience to disturbances in interpersonal relatedness and intersubjectivity (Mundy & Willoughby, 1996, 1998).

This logic suggests that research on joint attention may well have applications to numerous avenues of research on developmental psychopathology. For example, it may be useful to utilize measures of joint attention to identify disturbances of interpersonal processes related to the cross-generation transmission of risk for affective disorders (Goldsmith & Rogoff, 1997). It is also likely that joint attention theory and research will play a fundamental role in the future study of developmental pathological processes incurred in the context of maltreatment or neglectful caregiving. Disturbances in multiple developmental processes related to self-regulation, a sense of relatedness to others, social motivation, and social-cognitive processes may be foremost among the negative sequelae of abusive and neglectful caregiving (e.g., Cicchetti, 1996; Fonagy, 2003). We would argue that measures of joint attention reflect these multiple processes across development in infancy. Therefore, these measures may provide a complement to methods currently in use that will contribute to a better understanding of the interactive self-organizing and neurobehavioral processes that are involved in translating poor caregiving into chronic self-related pathology in some individuals.

Indeed, research is beginning to provide support for this conjecture. For example, work by Kroupina et al. (2003) suggests that caregiver neglect may have little impact on joint attention development in the 1st year of life. However, if neglect continues past 14 months, a specific deleterious effect may be observed on IJA development, but not necessarily RJA or IBR. Similarly, in some of our own research, Claussen et al. (2002) has reported that disorganized attachment, an extreme form of insecure attachment that has been associated with poor, inconsistent, and even punitive caregiving, is associated with a decline in IJA development between 12 and 18 months in children with in utero cocaine exposure. These studies suggest that there may be a sensitive period in IJA development relative to effects of extremes of impoverished caregiving. If so, understanding the nature of this sensitive period effect may be illuminating with regard to early developmental psychopathological process. Interestingly, Cicchetti, Rogosch, Maughan, Toth, and Bruce (2003) have also recently reported that maltreatment has a deleterious effect on theory of mind development and

that this effect may be especially pronounced for maltreatment that occurs in toddlerhood rather than early infancy or childhood. The apparent similarity of the sensitive periods of maltreatment effects observed for joint attention (Claussen et al., 2002; Kroupina et al., 2003) and ToM development (Cicchetti et al., 2003) is both remarkable and intriguing. At a minimum, the similarity across these studies may provide additional evidence for commonalities in processes that underpin joint attention and ToM development. More important, though, the combination of these findings suggests that the examination of both joint attention and ToM development in future longitudinal studies may be especially revealing with regard to the effects of maltreatment on critical social-cognitive, social-executive, and social-motivation processes in children.

In this regard, we would argue that factors that lead to a significant attenuation of IJA development may lead to an imbalance in social-emotional, self-organizing functions that may have a pernicious effect on the psychological and emotional development of children. This hypothesis is based on a constructivist view of development (Cicchetti, 2002; Cicchetti & Tucker, 1994; Piaget, 1952) and its relevance for understanding the role of joint attention in social development. Accordingly, behavior control, as well as the knowledge about self and other, necessary to adaptive social behavior is gained through an active process in which the individual continually structures and restructures experience and meaning through self-initiated behavioral/cognitive/emotional activity in social interactions. Piaget developed the notion that early cognitive development derived in large part from the actions infants took on objects in their world. Indeed, a major component of cognitive development was described in terms of the redescription of overt action (sensorimotor schemes) to covert mental representations of action (the semiotic function) in the first 2 years of life. For the most part, Piaget's formulations focused on the development of knowledge about objects, and unfortunately did not speak as clearly to social-cognitive or social-emotional development. Nevertheless, as we noted, it may be that the infant's capacity to initiate actions in social interaction, such as initiating joint attention bids, and to note both self-experience and social reactions to self-initiated action (e.g., integrative self-other monitoring), constitutes a major early constructivist process that facilitates typical social-emotional and social-cognitive development. With regard to the latter it may be that the early exercise and monitoring of self-initiated joint attention bids is critical to developing representations of self-intentions (Lau et al., 2004) that provide a critical comparative foundation for interpreting the intentions of others (Mundy,

2003, in press). An attenuation of the tendency to initiate joint attention bids, therefore, may not only be a marker of a negative effect of past pathological process, but also a marker of an ongoing disturbance in social constructivist developmental processes that contributes to subsequent layers of psychopathology over time and age (for discussion of this transactional perspective applied to Autism, see Mundy & Crowson, 1997; Mundy & Neal, 2001).

We would also suggest that recent theory and research on the frontal and temporal-parietal processes associated with joint attention (e.g., Henderson et al., 2002; Mundy, 2003; Vaughan & Mundy, in press) may contribute to research and theory on the neurodevelopmental effects of maltreatment (Cicchetti, 2002). If an outcome of maltreatment in some children is an attenuation of IJA and we can examine the neural correlates of IJA associated with social executive functions such as integrative self-other monitoring, then we may be able to better understand the neuropsychological sequelae of maltreatment. For example, if maltreatment is associated with IJA impairment but not the social attention management that is involved in RJJA (Claussen et al., 2002; Kroupina et al., 2003), it might be informative to undertake a sequence of imaging studies to determine if maltreatment is specifically associated with changes in frontal, self-system processes associated with IJA development, but spares aspects of social information (e.g., processing and following of eye gaze) and attention regulation processes associated with temporal functions.

The conceptual overlap of joint attention with the literature on temperament, caregiving, attachment, and social cognition may have also limited the recognition of the independent contributions that the study of joint attention may make to the field of developmental psychopathology. Some researchers may view joint attention simply as a by-product of these other domains of development. Therefore, connections between joint attention and social competence or psychopathology could be nothing more than an epiphenomenon of these more basic facets of social and emotional development. Examining this possibility is extremely important, and much more research will be needed before a firm verdict can be reached on this complex issue. However, research to date suggests that caregiver behavior alone may not completely explain all the relations between joint attention and developmental outcomes. For example, caregiver behaviors may not have as much impact on RJJA as on IJA (e.g., Claussen et al., 2002), but both types of joint attention have been related to social outcomes (Sheinkopf et al., 2004). Moreover, although complex connections exist between joint attention, temperament, attachment, and social cognition, the evidence available to date suggests that

the relations between joint attention and social-emotional outcomes in children cannot be reduced simply to mediation by these other domains of development (Sheinkopf et al., 2004; Vaughan et al., 2004).

Recall that the incremental validity for joint attention measures in this regard may, in part, reflect the nature of their assessment. Joint attention measures, such as the ESCS, provide multiple indices of the capacity of children to initiate and respond to social bids in the context of interactions with familiar or unfamiliar partners. Although other infant measures of emotional expressivity, motivation, executive attention management, and social cognition are available, the interactive context of joint attention measures lends them an ecological validity that suggests that they may at least complement other measures currently used to examine early social-emotional development. However, in addition to their ecological validity, the content of joint attention measures also likely makes contributions to their incremental validity.

To explore this issue a bit further, consider one contemporary theory linking attachment to social developmental outcomes in children and adults. In a brilliant integration of nativist (i.e., genetic) and social (i.e., attachment) models of development, Peter Fonagy (2003) has suggested that a primary adaptive function of attachment is to contribute to a mental mechanism that facilitates the understanding of internal states in self and others. With apologies for the oversimplification, Fonagy suggests that attachment process contributes to typical and atypical personality development by moderating constitutional neurodevelopmental processes involved in social-cognitive development. According to Fonagy, the social-cognitive mental mechanism that arises from the interaction of neurodevelopmental genotype and social, caregiving variation associated with attachment overlaps with theory of mind social cognition, but more clearly involves the capacity for social affective as well as social epistemological representations. Thus, Fonagy's Interpersonal Interpretive Mechanism (IIM) is a warmer version of the relatively coolly cognitive ToM module that many social-cognitive theorists have described.

Fonagy (2003, p. 15) describes the IIM as follows:

We conceive of IIM as the collection of neurocognitive mechanisms that are naturally selected to evolve under the influence of early social interactions predominantly with the attachment figure and that serve to mediate the impact of the quality of early relationships into adult personality functions.

So what are these neurocognitive mechanisms, or better yet, how do we measure them? Of course, we would suggest

that observation of joint attention skills provides one essential approach to the early measurement of “the neurocognitive mechanisms” in Fonagy’s model. Theoretically, joint attention skills reflect neurodevelopmental constructivist processes that have evolved to yield the early foundation for the development of the capacity for interpersonal interpretation (e.g., Mundy, 1995; Tomasello, 1995). This early foundation involves the social executive capacity for integrative self-other monitoring and the development of social cognition through the simulation of other minds (C. Frith & Frith, 1999; U. Frith & Frith, 2001; Mundy, 2003; Mundy et al., 1993). This social executive capacity may develop, to some extent, under the influence of early social interactions with the attachment figure. If so, research and theory on joint attention may provide a rich empirical and theoretical framework for the more detailed study of how caregiver influence and attachment process contribute to the development of IIM. Of interest, though, there was little if any overt recognition of the relevance of the literature on joint attention for examining the IIM developmental model incorporated into Fonagy’s seminal formulation. This illustrates the current *Zeitgeist*, which does not yet clearly recognize the potential utility of joint attention measurement for theory and research on early typical and atypical interpersonal development.

It may also be instructive to take current models of interpersonal development, which emphasize caregiver effects, and turn them around to examine development from alternative perspectives. For example, Fonagy (2003) suggests that attachment may moderate the neurocognitive development of interpersonal interpretation. If this is true, is the converse also possible? Can the neurocognitive development of interpersonal functions, such as infant joint attention, moderate the effects of attachment?

Although it is a truly unfortunate condition, Autism has the benefit of teaching us many lessons about human nature. One lesson is that differences in joint attention development and the related capacities for interpersonal interpretation and engagement may reflect differences in constitutional (genetically constrained) neurobiological developmental processes. This observation raises intriguing possibilities for future research and theory. Consider for the moment the notion that a genotype does not describe a definitive phenotypic expression of behavior. Rather, the genotype sets upper and lower limits, or a “reaction range,” for the expression of a behavioral phenotype (Waddington, 1962). Thus, children may vary on the range of effect that the environment has on their development of these skills. Accordingly, children with a low set point for the reaction range of their joint attention skill development may be es-

pecially at risk with respect to the potential detrimental effects of poor caregiving. Poor caregiving in these children may inhibit development to such an extent that joint attention skill acquisition falls below some critical level, leading to a clinically significant disturbance of self-constructivist behavior in social development. Alternatively, other children may have a higher constitutional reaction range for joint attention development. Among these children, poor caregiving may diminish their joint attention tendencies to some degree. However, their reaction range is such that even lower outcomes in these children are well above the criterion levels needed for adaptive self-constructivist social development. Therefore, these children may have sufficient reservoirs of the interpersonal capacity for joint attention that they can exercise in the context of alternative caregivers (e.g., other parent, relatives, or community adults such as preschool teachers). Thus, these children maintain sufficient positive social self-constructivist tendencies in interactions with alternative caregivers and other social partners (e.g., peers) to compensate for less than optimal primary caregiver attachment.

We previously described this model in terms of the “vulnerability hypothesis” of joint attention development (Mundy & Willoughby, 1996, 1998). That is, children at risk for developmental psychopathology because of environmental circumstance (e.g., poor caregiving, teratogen exposure) may display attenuated joint attention development as a group. However, within any at-risk group of infants and toddlers, individual differences in joint attention will be apparent, and the better development of infant joint attention will be a significant marker of constitutional neurodevelopmental factors associated with lower vulnerability to environmental pathogenic process within the group. The recent work of Sheinkopf et al. (2004) provided the first test of this hypothesis and demonstrated that individuals in an at-risk sample of cocaine-exposed infants who displayed better IJA and RJA skills at 12, 15, and 18 months received better teacher ratings of social behavior outcomes at 36 months of age. Unpublished work by Crowson (2001) and Block (2005) also suggests that better joint attention skill development, particularly IJA development, may moderate some of the negative effects of insecure attachment on early development in young children. Still, many more studies of this ilk will be needed before the significance of joint attention for developmental psychopathology, as well as typical development, may be fully appreciated. We look forward to the next generation of research on this issue and trust that it will yield fascinating and useful new perspectives on joint attention and typical and atypical interpersonal development.

ACKNOWLEDGMENTS

We would like to thank Danielle Thorp for her contributions to the section of this chapter on caregiver scaffolding. We would also like to dedicate this chapter to the memory of Elizabeth Bates, whose seminal thinking continues to enrich research and theory on joint attention, as well as numerous other areas of developmental science.

John Bowlby's (1969/1982, 1973, 1980) attachment theory provided an innovative and compelling account of the parent-child relationship and its influence on personality development. In contrast to psychoanalytic models that stressed instinctual drives and intrapsychic conflict, Bowlby provided a framework for understanding how children's early experiences in close relationships shape expectancies about the self and others and lead to strategies for maintaining access to an attachment figure. These aspects of personality are activated in situations of danger, challenge, or threat and provide the individual with strategies for managing and coping with stress. More extreme stress is generally thought to lead to more intense activa-

tion of the attachment system. In this sense, the child's emerging confidence in the availability of an attachment figure is thought to play a major role in shaping the stress regulatory aspects of personality. Ainsworth's pioneering study of a nonclinical sample of Baltimore infants and their mothers provided an empirical foundation for Bowlby's theory of personality development (Ainsworth, Blehar, Waters, & Wall, 1978).

Beginning in the 1980s, researchers began to explore the relation between individual differences in attachment and psychopathology in more severely disturbed populations of parents and children. Early studies tended to view infant attachment insecurity as a risk factor for the subsequent

emergence of psychopathology. These studies resulted in two key advances: First, researchers identified atypical forms of infant attachment, and second, the studies illustrated the need to understand attachment risk within the broader context of developmental models of psychopathology. During the past decade, spurred by the development of new attachment measures, researchers have begun to consider how insecure and atypical attachment organization in preschool, childhood, adolescence, and adulthood creates risk for psychopathology. The move to life span measures of attachment and the use of these measures as risk factors for psychopathology have further highlighted the need for a more comprehensive theoretical framework to guide construct validation and hypothesis testing.

Bowlby's (1973, 1988) concept of developmental pathways provides an important conceptual model for understanding the relation between attachment and psychopathology. Developmental pathways can be used as a general metaphor for tracking individual differences across development periods and for accounting for both normal and atypical developmental outcomes (Cicchetti, 1993; Rutter & Sroufe, 2000). A central task for the field of developmental psychopathology is to identify pathways that lead to psychopathology. Cicchetti and Rogosch (1996) have further elaborated the potential complexity of the pathways concept with the concepts of *equifinality* and *multifinality*. Equifinality suggests that there are multiple pathways to a particular disorder at a particular developmental period. For instance, adolescent Conduct Disorder may be distinguished between early- and late-onset versions based on different pathways leading to the disorder. Similarly, the concept of multifinality suggests that no single factor determines a subsequent pathway, but rather, the effect of a risk factor on a subsequent disorder will depend on both its timing and its relation to other risk factors.

We begin our review with a summary of Bowlby's thinking about attachment and developmental pathways. The developmental pathways model places attachment-related aspects of personality into a much broader theoretical framework that includes multiple levels of analysis and the continuing influence of the caregiving environment. In this levels of analysis approach, an individual's attachment organization continues to interact with and mutually influence the caregiving environment. This dynamic transaction shapes an individual's developmental trajectory from infancy through adulthood. Whereas responsive caregiving and secure attachment tend to maintain an individual on a more optimal trajectory, nonresponsive/disrupted care and insecure attachment move the individual toward less adap-

tive functioning. Moreover, Bowlby viewed the caregiving environment as influenced by contextual factors, including the larger family, community, and cultural contexts. In his view, an individual's pathway toward psychopathology is the product of processes operating at multiple levels of analysis.

After reviewing the theory of attachment and developmental pathways, we discuss research on attachment and psychopathology as framed by three levels of analysis: (1) attachment organization, (2) caregiving quality, and (3) caregiving context. In this multilevel model, risk for psychopathology may occur at the individual, relationship, or contextual levels, and at each of these levels the degree of risk may vary. We begin our review at the individual level of attachment organization and consider how attachment insecurity and disorganization create risk for psychopathology. Although the majority of studies have assessed attachment insecurity in infancy, new measures of attachment organization at later developmental periods have been tested as later risk factors. Next, we review studies that examine risk for psychopathology at the level of caregiving quality. These risk factors range from insensitive care (Ainsworth et al., 1978), to frightened or frightening behaviors (Main & Hesse, 1990), to attachment disruptions and abusive parenting. Finally, we consider risk for psychopathology at the level of the caregiving context. Contextual risk factors include family violence, poverty, and parental psychopathology, all of which may work to decrease caregiving quality and increase attachment risk.

In the next part of the chapter, we describe different approaches to modeling the ongoing transactions among attachment, caregiving quality, and contextual risk. Although many of the early studies of attachment and psychopathology used relatively simple main effects models that viewed attachment insecurity as a risk factor for psychopathology, later studies have moved toward more complex models. Additive risk models took into account multiple factors in addition to attachment insecurity and have evolved toward more sophisticated models of transactional processes such as mediation, diathesis-stress, and early experience. Mediation models hold promise for helping investigators to distinguish attachment from nonattachment risk for psychopathology. Diathesis-stress models suggest that attachment insecurity is most likely to result in psychopathology under conditions of high stress. This model elaborates on the view of attachment as a stress regulatory system and suggests that symptoms are most likely to emerge when attachment-related coping breaks down.

Finally, early experience models require longitudinal designs and test the claim that early experience makes a unique and lasting contribution to later adaptation and psychopathology (Sroufe, Carlson, Levy, & Egeland, 1999). In the last part of our chapter, we use the developmental pathways model in conjunction with consideration of levels of analysis to point to important areas for further research.

ATTACHMENT AS A STRESS REGULATORY SYSTEM: A BEHAVIORAL SYSTEMS APPROACH

The cornerstone of Bowlby's theory of attachment was the notion, borrowed from ethology, of a "behavioral system." A behavioral system is a species-specific system of behaviors that leads to certain predictable outcomes at least one of which contributes to the individual's reproductive fitness. The concept of the behavioral system involves inherent motivation to maintain a set goal; there is no need to view component behaviors as the by-product of any more fundamental processes or "drive." In the first volume of his attachment trilogy, Bowlby (1969/1982) proposed a theory of human personality and relationships that drew on the ethological and evolutionary thinking of the time. Bowlby's behavioral control systems model of personality focused on four major behavioral systems: attachment, caregiving, fear, and exploration. At the level of personality organization, the dynamic relationship among these behavioral systems can be thought of as a predisposition or strategy for managing and coping with stress.

Bowlby conceived of attachment as a control system that continually monitors the availability of an attachment figure. The attachment system becomes most active under two conditions related to activation of the fear system, perceived threats to an attachment figure's availability and perceived danger in the environment, and one condition involving the exploratory system: perceived challenge in situations involving exploration and novelty. Activation of the attachment system typically results in behaviors designed to reestablish contact with the attachment figure or to restore confidence in the attachment figure's availability. Bowlby (1969/1982) proposed that the level of attachment activation varies as a function of perceived threat or challenge.

The child's appraisal of danger, challenge, or threat to an attachment figure's availability changes dramatically with development. Whereas in infancy physical separations in strange environments are appraised as threats to the caregiver's availability, in later developmental periods

physical separations are rarely perceived as a threat to availability due to the child's increased representational, communicative, and planning capability. In later developmental periods, unplanned disruptions of the relationship or verbal threats of rejection or abandonment are more likely to be perceived as threats to the caregiver's availability (see Kobak, Cassidy, & Ziv, 2004). Developmental changes also alter appraisals of danger and challenge. Moreover, the individual's growing competency and mastery of the environment continually changes the types of tasks that are likely to be perceived as challenging, and appraisals of danger are increasingly shaped by cultural information and associative learning.

Bowlby's view of personality organization is based on a dynamic conception of how the attachment behavioral system interacts with other behavioral systems, such as exploration, fear, and caregiving. The fear and attachment systems function in a synchronous manner. When an individual perceives clues to danger in the environment, not only is the fear system and a fight/flight response activated, but the attachment system is simultaneously activated and the individual copes with danger by seeking protection from a caregiving figure. Threats to the availability of an attachment figure also serve to activate the fear system. Thus, fear increases activation of the attachment system, and the individual copes with fear by regaining access to protection or safety offered by an attachment figure. In this sense, attachment can be understood as a biologically evolved coping strategy for managing fear and distress. The exploratory system has an antithetical relation to the attachment and fear systems. The emergency responses associated with high activation of fear and attachment take precedence over exploration. However, when access to an attachment figure is assured, exploration can take precedence over safety-related concerns.

The dynamic interplay among the attachment, fear, and exploratory systems leads to two very important hypotheses about how attachment influences adaptation. On the one hand, the attachment system serves a major protective and coping function when the individual is faced with situations of danger (referred to as the "safe haven" function of the attachment relationship). Second, confidence in the caregiver's availability is thought to enhance the child's ability to explore in novel or challenging situations (the "secure base" function).

Consideration of the secure base and safe haven functions provides general guidelines for understanding how secure attachment promotes successful coping with stress and exploration of the environment. Both functions of

attachment suggest that attachment processes are most important in contexts involving danger and challenge. Whereas situations of challenge are likely to activate the attachment system at fairly low levels, situations of danger are likely to activate attachment at fairly high levels. Although individual differences in attachment may be observed in subtle ways in contexts involving challenge or exploration, they are most likely to be evident in contexts involving danger or threat.

Attachment Organization as an Aspect of Personality: Implications for Stress Regulatory Strategies

During the past decade, researchers have drawn increased attention to the stress regulatory function of attachment (Fearon & Belsky, 2004), and a growing body of research on the behavioral and psychophysiological correlates of individual differences in attachment security highlights the importance of the stress regulatory function of attachment (Burgess, Marshall, Rubin, & Fox, 2003; Hertsgaard, Gunnar, Erickson, & Nachmias, 1995; Spangler & Grossman, 1993; Stevenson-Hinde & Marshall, 1999). In fact, Ainsworth and colleagues' (1978) Strange Situation procedure, the central assessment tool of individual differences in infant attachment security, uses multiple contextual cues (i.e., an unfamiliar environment, an unfamiliar adult, and physical separation) to elicit high levels of infant distress and corresponding activation of the attachment system. Based on her understanding of the interplay among the attachment, exploration, and fear behavioral systems, Ainsworth identified three major attachment patterns: secure, avoidant, and resistant. She identified these patterns by observing how infants used their caregivers to manage separation distress. Infants judged secure are able to utilize their caregiver as a resource in managing stress. They signal distress directly, seek contact or interaction with the caregiver, and derive comfort from the interaction.

In contrast, the avoidant pattern of behavior is marked by less obvious signals of distress and attempts to reduce the activation of the attachment system through diversionary activities, such as ignoring the caregiver or focusing on objects without obvious interest or engagement. As a result, the caregiver is not utilized as a resource for coping with distress and the attachment system is deactivated through diversionary strategies. The resistant pattern is also marked by ineffective use of the caregiver for coping with distress. These children openly display distress signals and may seek contact with the caregiver, but contact is not effective in reducing distress. As a result, these chil-

dren appear to be characterized by a chronic activation of the attachment system that simultaneously reduces or inhibits exploratory activity. Both of the anxious strategies, avoidant and resistant, are marked by the lack of coordination between the attachment, fear, and exploratory systems. Avoidant infants are likely to seem less fearful and minimize attachment behaviors, and resistant infants are likely to seem distressed and maximize their attachment behaviors (Main, 1990).

These consistently observed patterns of behavior under the stressful conditions created by Ainsworth's Strange Situation procedure illustrate differing organizations for how children coordinate the attachment system with the fear and exploratory behavioral systems (Sroufe & Waters, 1977). Drawing on Bowlby's concept of internal working models, Ainsworth and her colleagues (1978) suggested that attachment patterns were organized by infants' expectations or forecasts of the availability and responsiveness of their caregivers. Much of Ainsworth's observational work was designed to show that the expectations that guided the infant's behavior in the Strange Situation were derived from the quality of actual interactions that the child had with his or her caregiver. Her finding that sensitive caregiving during the first 12 months predicted a secure attachment pattern in the Strange Situation supported Bowlby's contention that the child's attachment organization is shaped by experiences with caregivers. Further support linking attachment organization in the Strange Situation to sensitive caregiving has come from a number of subsequent studies (see Belsky, 1999; DeWolff & van IJzendoorn, 1997, for reviews).

The child's expectations (or "internal working model") of a caregiver's availability and responsiveness form the core of attachment-related features of the child's personality. This attachment organization is likely to be particularly important in guiding the child's behavior in stressful situations and will influence the degree to which the child is able to effectively manage stress. If the child is secure or confident in the caregiver's availability, he or she can maintain a lower level of attachment activation and corresponding increased ability to attend to and explore the environment (Bowlby, 1973, 1979). Confident expectations also allow the child to effectively communicate his or her needs and use the caregiver as a source of comfort when distressed (Kobak & Duemmler, 1994).

These relatively primitive models and their associated behavioral strategies for managing distress that are observed in the Strange Situation become more sophisticated and elaborated with development. As the child matures, the

confident expectations that guide secure behavior in the Strange Situation become more refined and integrated with expectancies that the child has developed in other attachment relationships. Most important, expectations about the caregiver's likely behavior create the context within which the child develops an emerging sense of self. The child's sense of efficacy in managing distress or challenging situations, along with his or her view of the self as worthy of support, become central mechanisms through which the attachment organization is carried forward to new relationships and contexts beyond the immediate family (Bowlby, 1973; Bretherton & Munholland, 1999).

Attachment and Developmental Pathways

In considering developmental pathways, Bowlby (1979, p. 104) wrote:

In the picture of personality functioning that emerges there are two main sets of influences. The first concerns the presence or absence, partial or total, of a trustworthy figure willing and able to provide the kind of secure base required at each phase of the life cycle. These constitute the external, or environmental influences. The second set concerns the relative ability or inability of an individual, first, to recognize when another person is both trustworthy and willing to provide a base and, second when recognized, to collaborate with that person in such a way that a mutually rewarding relationship is initiated and maintained. These constitute the internal, or organismic influences. Throughout the life cycle the two sets of influences interact in complex and circular ways.

Continuity and Change

Drawing on Waddington's (1957) epigenetic model of development, Bowlby conceived of the individual's attachment organization as part of a continuing interaction with the caregiving environment. This transaction shapes an individual's pathway, with some individuals moving along adaptive pathways and others branching in less optimal directions. In the last chapter of the second volume of the attachment trilogy, Bowlby (1973) formalized a model of the complex and changing relations between personality and the caregiving environment. This model posits that attachment processes operate at multiple levels. At the *individual* level, attachment organization provides a set of expectancies and regulatory strategies that becomes increasingly stable with development. At the environmental level, the availability and responsiveness of the caregiver play a continuing role in providing support and influencing expecta-

tions for self and others. At a third level, both the child and the caregiver are influenced by the wider family context. The context can support or reduce the caregiver's responsiveness and ability to protect the child from danger in the environment.

Although both attachment organization and the caregiving environment channel an individual along a particular pathway and thus tend to account for continuity in development, both are subject to change. Caregiving quality may change with stressors or supports in the family environment and subsequently influence the child's confidence in the caregiver and the child's attachment security. Change in the caregiving environment may move the child's pathways in either more positive or more negative directions. In this sense, a pathways model requires ongoing assessment of the child's attachment organization, the quality of care, and the wider family context. Further change in attachment organization should be "lawful" or predicted by changes in caregiving quality or the family context.

Environmental Sensitivity

A final aspect of Bowlby's model has often been overlooked. Bowlby posited that attachment organization was most sensitive to the caregiving environment early in development and gradually became more stable and resistant to change. This environmental sensitivity hypothesis suggests that an individual's pathway is likely to be more strongly influenced by caregiving quality early in development. Whereas in early development, attachment organization is very sensitive to the caregiving environment, by adolescence and adulthood, attachment organization has become a more stable factor and plays a larger role in maintaining an individual on his or her developmental pathway. Each of these core premises of a pathways models—levels of analysis, continuity and change, and early environmental sensitivity—provides important guidance to modeling the pathways that lead to psychopathology.

Attachment Organization as a Source of Continuity

Much attachment research has emphasized the extent to which infant attachment organization creates continuity in a child's developmental pathway (Main, Kaplan, & Cassidy, 1985; Waters, Merrick, Treboux, Crowell, & Albersheim, 2000). Such continuity between infancy and later developmental periods is consistent with Bowlby's notion of *homeorhesis*, or the self-sustaining nature of personality. Attachment organization may contribute to continuity in a child's developmental trajectory in several ways. First,

continuity may be maintained by the expectations that the child carries forward to new situations. The expectancies for self and others and stress regulatory strategies that the child develops within the attachment relationship are thought to generalize beyond the relationship to influence adaptation in peer and school environments (Sroufe, 1983; Sroufe, Schork, Motti, Lawroski, & LaFreniere, 1985). Early attachment organization may also play an important role in shaping the child's behavior in later developing periods and eliciting reactions from others that tend to confirm and perpetuate the child's expectancies.

A second way in which attachment organization may serve to maintain a developmental pathway is through influence on the caregiver-child relationship. The strategies for regulating attachment that the child develops in infancy may influence how the caregiver engages the child in subsequent developmental periods. For instance, avoidant attachment has been viewed as a strategy designed to minimize conflict with a potentially rejecting caregiver (Main & Weston, 1981). However, by not signaling distress, the child may elicit caregiver behavior that confirms the child's expectancies that the caregiver will not respond. Further, isolation or dysfunctional anger that may accompany an insecure strategy may result in behavior that further elicits rejections by the caregiver.

Lawful Discontinuity in Attachment Organization

Despite theoretical and empirical support for the contribution of attachment organization to continuity in a child's developmental trajectory, there is substantial evidence that attachment organization remains open to change. This is particularly true of early developmental periods when attachment organization is subject to substantial change and instability. During the infant period, change is evident over the relatively short period of 6 months. In the Minnesota longitudinal study, 62% of children remained stable in attachment security between 12 and 18 months, and 28% changed. Some of the change in attachment organization was accounted for by caregiving variables. For instance, the move from secure to insecure was associated with caregivers who experienced less joy in feeding their infants (Egeland & Farber, 1984) and the move from insecure to secure occurred when mothers reported lower levels of negative life events (Vaughn, Egeland, Sroufe, & Waters, 1979). Over longer periods change in attachment organization become more likely.

The evidence for lawful discontinuities in attachment security (Belsky, Fish, & Isabella, 1991) is consistent with Bowlby's view of attachment. His pathways model stressed that attachment organization remains sensitive to the care-

giving environment throughout the years of immaturity, and the working models that form the core of attachment organization need to be continuously updated and revised to promote successful adaptation to the environment.

The Environmental Responsiveness of Attachment Organization

According to Bowlby, internal aspects of personality continuously interact with the caregiving environment. While the child's attachment organization can influence the caregiver, the caregiver continues to influence the child. As a result, the working models that form the core of the child's attachment organization are open to updating and revision to accommodate new information. This process of updating and revising models includes incorporating developmental changes in the child-caregiver relationship that allow more complex and sophisticated coordination of activities (Thompson, 1999). Updating may also accommodate changes in the quality of care available to the child. Thus, a child with secure attachment in infancy may encounter a major disruption of a relationship with a caregiver during the preschool period. Alternatively, a child with insecure attachment may find that a parent becomes more available, or may form a relationship with a new caregiver who is trustworthy and who behaves in ways that are inconsistent with previous models. To accommodate these developmental and relational changes, the child must revise and update his or her working models and related strategies.

The capacity for updating and revising models changes substantially with development. Bowlby (1973, p. 367) posited that attachment organization would have "a fair degree of sensitivity to the environment, especially to family environment, during the early years of life, but a sensitivity that diminishes throughout childhood and is already very limited by the end of adolescence." This environmental sensitivity hypothesis suggests that the child's early experience with caregivers has a unique and important role in shaping attachment organization, and that this influence gradually decreases with development.

Two hypotheses follow from the concept of environmental sensitivity. First, attachment organization should be less stable during early developmental periods and become more stable in later developmental periods. Further, to the extent that there is continuity in attachment organization in infancy and early childhood, much of this continuity is likely to be attributable to stability in the caregiving environment.

Second, the relative contributions that attachment organization and the caregiving environment make to an indi-

vidual's pathway will change across development (see Fraley & Brumbaugh, 2004). During the early years, measures of the caregiving environment should account for relatively more variance in developmental outcomes; during later years, attachment-related aspects of the child's personality should become more important as the contribution of the caregiving environment gradually diminishes. Further, to the extent that there is continuity in attachment organization in infancy and early childhood, much of this continuity is likely to be attributable to stability in the caregiving environment.

Empirical tests of the environmental sensitivity hypotheses depend on longitudinal designs and simultaneous measurement of both attachment organization and the caregiving environment. Most of the initial longitudinal studies have tended to focus assessment on attachment organization without strong measurement of the caregiving environment. Further, the more extensive focus on attachment organization raises a number of questions about measurement error and the validation of the measures in the post-infancy period (Weinfield, Sroufe, Egeland, & Carlson, 1999). Although longitudinal studies that measure individual differences in attachment security across developmental periods are limited, there is some evidence that measures of attachment security become more stable at later developmental periods.

Early studies of relatively small middle-class samples suggested fairly high rates of stability in Strange Situation classifications between 12 and 18 months (Waters, 1978). However, as researchers began to study larger and more diverse samples, estimates for 12- to 18-month stability were substantially reduced (Barnett, Ganiban, & Cicchetti, 1999; Egeland & Erickson, 1987; Egeland & Farber, 1984; Lyons-Ruth, Repacholi, McLeod, & Silva, 1991; Thompson, Lamb, & Estes, 1982; Vondra, Hommerding, & Shaw, 1999). More recent studies examining attachment over 12- to 24-month periods and using preschool classification of attachment organization suggest modest stability in attachment organization between the infant and toddler periods (National Institute of Child Health and Human Development [NICHD] Early Child Care Research Network, 2001; Seifer et al., 2004; Vondra, Shaw, Swearingen, Cohen, & Owens, 2001). Lower rates of stability would tend to support the environmental sensitivity hypothesis, particularly in circumstances where the quality of the care was subject to change. However, studies that assess both attachment organization and the quality of caregiving over time are needed to adequately address this question.

The environmental sensitivity hypothesis predicts relatively greater stability in attachment organization at later

developmental periods. Tests of this hypothesis have been hindered by the lack of standard measures for assessing attachment organization in childhood and early adolescence (Greenberg, 1999; Thompson & Raikes, 2003). However, by middle adolescence through adulthood, Main and Goldwyn's (1998) classification of states of mind with respect to attachment in the Adult Attachment Interview (AAI) has been widely accepted as a measure of attachment-related aspects of personality. To date, two studies have examined stability of the AAI over 2 years. These studies cover the same time frame as the infant to toddler studies. They also provide an important point of comparison with the infant and toddler studies in terms of Bowlby's concept of decreasing environmental sensitivity. In one study of newlyweds from low-risk environments, 85% maintained the same secure/insecure AAI classification across 2 years (Crowell, Treboux, & Waters, 2002). In another study, substantial stability over 2 years again emerged in a sample of moderately at-risk adolescents (Allen, Boykin McElhaney, Kuperminc, & Jodl, in press).

In summary, the comparison of studies examining stability of attachment organization during different developmental periods lends support to Bowlby's notion that attachment-related aspects of personality become more stable and less sensitive to the caregiving environment by late adolescence and adulthood. However, even in these later developmental periods, there is evidence that attachment organization remains open to accommodating changes in the caregiving environment.

The Caregiving Environment and Developmental Pathways

Describing the caregiving environment, Bowlby (1979, p. 133) wrote:

The behavior of parents, and of anyone else in a care-giving role, is complementary to attachment behavior. The roles of the caregiver are first to be available and responsive as and when wanted and, second, to intervene judiciously should the child or older person who is being cared for be heading for trouble.

The evidence for lawful discontinuity and early environmental sensitivity supports Bowlby's developmental pathways model and the continuing role of the caregiving environment in maintaining a child on a developmental trajectory. Bowlby (1969/1982) postulated that the caregiver's behavior toward the child is organized by a caregiving behavioral control system whose set goal is protection of the child and ensuring the child's reproductive

fitness. George and Solomon (1999) have noted that this aspect of attachment theory has not received a great deal of attention from attachment researchers. In his developmental pathways model, Bowlby clearly emphasized the ongoing importance of the caregiving environment in shaping developmental trajectories.

In spite of the theoretical importance that Bowlby assigned to the caregiving environment, it has received relatively little attention from researchers who study attachment beyond infancy. One of the problems in studying caregiving beyond infancy is that the boundaries are poorly defined between what constitutes “available and responsive care” and what deals with other aspects of caregiving in the extensive literature on parenting. For instance, although establishing clear rules and expectations for the preschooler is widely accepted as a part of optimal or authoritative parenting, many may view this as separate and independent of attachment-related caregiving. Yet, much of optimal parenting behavior may be incorporated in what Bowlby viewed as available and responsive care in the fourth stage of the attachment relationship, the “goal-corrected partnership” (see Kobak & Duemmler, 1994, for a discussion). Yet, despite the ambiguities in defining the boundaries between parenting in general and attachment-related caregiving, attachment theory provides several useful guidelines for conceptualizing the caregiving environment.

The *quality of care* that is available to the child represents the most proximal aspect of the caregiving environment. Bowlby (1979, p. 104) conceived of the quality of care in terms of the “presence or absence, partial, or total, of a trustworthy figure willing and able to provide the kind of secure base required at each phase of the life cycle.” The quality of care has been most extensively investigated during infancy. In this period, Ainsworth developed measures of caregiver sensitivity that captured important aspects of Bowlby’s notion of available and responsive caregiving, particularly at times when the child’s attachment system is active. Attachment researchers have relied extensively on Ainsworth’s measures of caregiver sensitivity to assess the quality of the caregiving environment. These measures have been effective at distinguishing between infants judged secure and insecure in the Strange Situation (for a review, see Belsky, 1999; DeWolff & van IJzendoorn, 1997).

The surrounding family or *caregiving context* represents a more distal component of the caregiving environment. Caregiving context may either directly influence attachment processes affecting the child’s attachment organization or may indirectly influence the quality of care that is available to the child. A variety of factors have

been considered as possible contextual influences on the child’s attachment security. These factors fall into three broad categories: (1) personality and psychological health of the caregiver (see Belsky, 1999, for a review), (2) marital or adult attachment relationships (Owen & Cox, 1997), and (3) stress associated with poverty (including educational attainment, income-to-needs ratio, minority status, and stressful life events; van IJzendoorn, Schuengel, & Bakermans-Kranenburg, 1999).

The AAI has introduced an additional element into consideration of the caregiving environment. By providing a measure of the caregiver’s attachment organization, new questions can be considered about how the caregiver’s attachment may mediate or moderate the effects of caregiving quality and caregiving context on the child. A “free to evaluate” or secure state of mind in the AAI has been linked to infant attachment organization, and it may also play an important role in enhancing supportive family relationships and buffering the child from contextual stressors.

Summary

Bowlby’s developmental pathways model specifies three major levels of analysis: *attachment organization* at the individual level, *quality of care* at the relationship level, and *caregiving context* at the family level. A fully specified developmental pathways model requires assessment of each of these levels at each developmental period. To successfully test the model, researchers need to assess attachment organization, caregiving quality of care, and contextual supports and challenges experienced by both the child and the caregiver. Not only is assessment of current functioning at each level of analysis required, but a complete pathways model also requires assessment of prior functioning at each level. Only by following an individual across developmental periods is it possible to adequately map continuity and discontinuity in an individual’s developmental pathway.

DEVELOPMENTAL PATHWAYS TO PSYCHOPATHOLOGY: A REVIEW OF RESEARCH

The developmental pathways model can be used to consider a wide range of developmental outcomes. For instance, Bowlby was particularly interested in pathways that would lead to the development of a “healthy self-reliant person.” An essential ingredient of a self-reliant personality is “a capacity to rely trustingly on others when occasion de-

mands and to know on whom it is appropriate to rely” (1973, p. 359). Empirical support for this model comes from studies linking attachment and caregiving quality to broad domains of socioemotional competence (Belsky & Cassidy, 1994).

Psychopathology represents a complex developmental outcome. Whereas secure attachment organization can be seen as a protective factor or one that reduces the likelihood of pathways leading to psychopathology, insecure attachment has been viewed as a risk factor or one that increases the likelihood of disorder. The pathways model places attachment risk within a larger context of multiple risk factors that operate at multiple levels and that transact with each other in ways that may increase or decrease the likelihood of psychopathology. A multilevel approach that assesses *attachment organization*, *caregiving quality*, and *caregiving context* creates an opportunity to more fully understand how attachment related risk contributes to the development of psychopathology.

A first step toward a more comprehensive model of attachment and psychopathology requires identification of risk at each level of analysis in each developmental period. The degree of risk may vary along several dimensions, including the severity of particular risk factors, persistence or risk factors over time, and the accumulation of numbers of stressors. In reviewing studies of attachment and psychopathology, we attempt to identify a continuum of risk at each level of analysis. Current findings can inform future studies of attachment and psychopathology and lead to greater specificity about the conditions under which developmental pathways lead to psychopathology.

Our review begins with attachment-related personality structure as a risk factor for psychopathology. This level of analysis has received by far the most research attention. In reviewing attachment assessments in infancy, preschool, adolescence, and adulthood, we identify a continuum of personality risk for psychopathology. We pursue a similar strategy as we consider risk for psychopathology at the levels of caregiving quality and caregiving context.

ATTACHMENT ORGANIZATION AND PSYCHOPATHOLOGY: A CONTINUUM OF INDIVIDUAL RISK

A guiding hypothesis in most studies of attachment and psychopathology is that insecure attachment organization increases risk for disorder. Initial tests of this hypothesis often relied on low-risk samples of convenience, and for the most part, these studies provided minimal support

for the hypothesis (Greenberg, 1999; Sroufe, 1988). In several samples, children with insecure attachments did not develop psychopathology, and secure attachment patterns did not reduce risk for the emergence of symptoms (Bates, Maslin, & Frankel, 1985). However, as attachment researchers began to study samples at greater risk for psychopathology as a result of poverty, parental psychopathology, or clinical status, more support for attachment insecurity as a risk factor emerged. These samples with higher rates of psychopathology also led investigators to expand Ainsworth's classification of infant attachment patterns to include atypical behaviors (Crittenden, 1985; Lyons-Ruth, Connell, Zoll, & Stahl, 1987; Main & Solomon, 1990; Radke-Yarrow, Cummings, Kuczynski, & Chapman, 1985) and patterns of atypical behavior in the newer measures of attachment organization in older children and adults (Cassidy, Marvin, & MacArthur Working Group on Attachment, 1992; Crittenden, 1992, 1994; Main & Goldwyn, 1998).

Measurement of attachment organization is a critical problem for researchers. Studies of attachment in infancy have used Ainsworth's Strange Situation (Ainsworth et al., 1978) as a standard and validated measure of early attachment organization. By contrast, measures of attachment organization in preschool and childhood are not as well validated or standardized. For instance, in the preschool period, researchers have relied on behavioral observations using either the MacArthur or Crittenden Preschool Systems or the Attachment Q-Sort (Waters & Deane, 1985). Childhood studies have used both narrative (Verschuere & Marcoen, 1999) and reunion procedures to assess attachment (Main & Cassidy, 1988). Adolescent and adult studies have used the AAI (Allen & Land, 1999; Hesse, 1999) or a variety of self-report measures. Further validation of these newer measures remains an important topic for further research.

Despite the difference in measurement strategies, most systems have continued to assess patterns of atypical attachment behavior. The discovery of disorganized/disoriented behavior in the Strange Situation (Main & Hesse, 1990; Main & Solomon, 1990) has led to a new generation of studies that have examined this behavior as an additional potential risk for subsequent psychopathology. Atypical patterns of attachment have also been identified in the Main and Cassidy (1988) procedure with children who had been disorganized as infants showing controlling/punitive or controlling/caregiving patterns with their mother. Finally, in the AAI, a variety of atypical discourse patterns have been identified (e.g., the Unresolved Loss and Trauma classification, the Preoccupied with Trauma subclassification,

and the Insecure/Cannot Classify classification). Lyons-Ruth, Yellin, Melnick, and Atwood (2003) have recently added to these atypical AAI patterns with ratings of hostile/helpless aspects of discourse. These atypical patterns have been most prevalent in high-risk or clinical samples and suggest that individuals with atypical attachment organization may be at increased risk for psychopathology.

Infant Attachment and Psychopathology

Many of the early studies of attachment and psychopathology relied on normal middle class samples that generally are exposed to less caregiving or contextual risk than clinical or low income samples. Later studies of high risk or clinical samples better illustrate the transactions between attachment, caregiving and contextual risk, and the role of developmental pathways to psychopathology.

Low-Risk Samples

A summary of studies of infant attachment and psychopathology can be found in the first section of Table 10.1. Studies that relied primarily on normal samples of convenience generally do not have any indicators of contextual risk and are considered to be low-risk samples. These low-risk studies generally produced mixed results. Whereas Bates and his colleagues (1985) found no relation between anxious attachment measured at 13 months and externalizing symptoms at age 3, Fagot and Kavanagh (1990) reported that avoidant attachment was associated with a broad composite measure of problem behaviors assessed at four different time points when children were between 24 and 48 months of age. In another study, both avoidant and resistant attachment were associated with externalizing symptoms at age 6, though prediction of symptoms was enhanced by maternal reports of life stress (Lewis, Feiring, McGuffog, & Jaskir, 1984).

Greenberg (1999) has noted that low-risk samples put investigators at a disadvantage in detecting a relation between attachment and psychopathology. First, low base rates of psychopathology make it more difficult to detect statistically significant effects and increase the threat of Type II errors. A further limitation of the early low-risk studies is that they were conducted before it was possible to separate out the children with disorganized attachment. An additional limitation of some of the low-risk studies is that the absence of caregiving and contextual risk may serve as unspecified third variables that buffer children from risk associated with insecure attachments. As a result, the findings

from these low-risk studies have limited value in explaining the relations between attachment and psychopathology.

High-Risk Samples: Behavior Problems and Global Psychopathology

In contrast to low-risk samples, high-risk samples are at increased risk for psychopathology as a result of low socioeconomic status (SES) or parental adjustment problems. Low SES is thought to increase risk by increasing children's exposure to stressors associated with poverty, including financial strain, residential mobility, violence, single-parent status, and lower levels of maternal education. A variety of parenting adjustment factors, including depressive symptoms, lower levels of social support, teen parenting, and substance abuse, also covary with poverty. These factors have all been identified as main effects for child psychopathology, especially externalizing symptoms.

Most studies of infant attachment using high-risk samples have focused on disruptive, aggressive, and externalizing symptoms as outcomes. The Minnesota Parent-Child Project represents the first major longitudinal investigation of infant attachment and psychopathology in a high-risk sample (see Sroufe, Egeland, Carlson, & Collins, 2005). These investigators were the first to report that avoidant infant attachment increased children's risk for behavior problems and for teacher-reported hostility, isolation, and lack of compliance at age 4 (Erickson, Sroufe, & Egeland, 1985). Avoidant infant attachment continued to predict behavior problems in elementary school, with the effects being strongest for boys and aggressive behaviors (Renken, Egeland, Marvinney, Mangelsdorf, & Sroufe, 1989). In that study, assessment of contextual risk using measures of maternal life stress and relationship support during infancy and early childhood substantially improved the prediction of middle school behavior problems.

In a further follow-up on the Minnesota sample, Aguilar, Sroufe, Egeland, and Carlson (2000) used attachment and early caregiving variables to investigate Moffitt's (e.g., 1990, 1993) theory regarding early- versus late-onset adolescent antisocial behavior. The early-onset persistent group was distinguished by indices of socioemotional history, including the presence of avoidant attachment at 12 and 18 months. Although avoidant attachment contributed to identifying early onset of adolescent antisocial behavior, this group was distinguished by a broad array of psychosocial risk during infancy and early childhood, including physical abuse, caregiver unavailability, and life stress.

A growing number of studies suggest that disorganized infant attachment may be an important risk factor for later

TABLE 10.1 Attachment and Psychopathology in Infancy, Preschool, Childhood, Adolescence, and Adulthood

Study	Outcome Symptoms	Sample and Study Characteristics	Risk Factors		
			Attachment	Caregiving	Context
Infant Attachment and Psychopathology					
Fagot & Kavanagh (1990)	Problem Behavior (24, 27, 30, and 48 months)	Longitudinal (N = 109)	Avoidant (Strange Situation at 18 months)	None	None
Lewis et al. (1984)	Externalizing at age 6 for boys	Longitudinal (N = 113)	Insecure (Strange Situation at 12 months)	None	Life stress
Bates et al. (1985)	Externalizing at age 3	Longitudinal (N = 120)	Insecure (Strange Situation at 13 months)	Insensitivity	Infant temperament Irritability
Belsky & Fearon (2002a)	Problem behaviors at 3 years	NICHD sample Longitudinal (N = 1015)	Insecure attachment (Strange Situation at 15 months)	None	Cumulative risk factors
Fearon & Belsky (2004)	Attentional performance (54 months)	NICHD sample Longitudinal (N = 918)	Insecure, disorganized (Strange Situation at 15 months)	None	Cumulative risk factors
Goldberg et al. (1995)	Internalizing and externalizing at age 4	Longitudinal (N = 145)	Avoidant (Strange Situation at 12–18 months)	None	Medical risk: Cystic fibrosis or congenital heart defects
Belsky & Fearon (2002b)	Problem behaviors (36 months)	NICHD sample Longitudinal (N = 1,015)	Insecure (Strange Situation at 15 months)	Sensitivity (24 months)	None
Shaw & Vondra (1995)	Behavior problems at age 3	Longitudinal (N = 100)	Insecure (Strange Situation at 12 and 18 months)	Maternal parenting practices	Low SES
Shaw et al. (1996)	Disruptive behavior at age 5	Longitudinal (N = 100)	Disorganized (Strange Situation at 12 months)	None	Maternal aggression, difficult temperament, low SES
Shaw et al. (1997)	Internalizing (36 months)	Longitudinal (N = 86)	Disorganized (Strange Situation 12 months)	Parenting conflicts	Parenting stress, negative life events, low SES
Munson et al. (2001)	Externalizing problems at age 9	Longitudinal (N = 101)	Avoidant and disorganized (Strange Situation at 12–18 months)	None	Teen mothers, maternal depressive symptoms
Ogawa et al. (1997)	Dissociation at age 17	Longitudinal (N = 168)	Avoidant and disorganized (Strange Situation at 12 months)		Low SES, chronicity and severity of trauma exposure
Warren et al. (1997)	Anxiety disorder at age 17, K-SADS	Longitudinal (N = 172)	Ambivalent (Strange Situation at 12 months)	None	Low SES, maternal anxiety
Renken et al. (1989)	Internalizing and externalizing in middle childhood	Longitudinal (N = 191)	Insecure (Strange Situation at 18 months)	Inadequate or hostile parenting	Low SES, chaotic or stressful life events
Aguilar et al. (2000)	Early onset adolescent antisocial behavior	Longitudinal (N = 180)	Avoidant attachment (12 and 18 months)	Inadequate care (6, 24, 36, and 4months) Low SES, maternal depression, stressful life events	Low SES, maternal depression, stressful life event

symptom outcomes. In contrast to the avoidant and resistant forms of insecure attachment, infant disorganized attachment behavior does not show the comprehensible strategic organization characterizing other patterns of attachment behavior. Thus, the term *disorganized* refers to the apparent lack of a consistent strategy for organizing responses to the need for comfort and security when under stress (Main & Solomon, 1986). The particular combinations of disorganized behaviors observed in infancy tend to be idiosyncratic and diverse but include apprehensive, helpless, or depressed behaviors, unexpected alternations of approach and avoidance toward the attachment figure, and other conflict behaviors, such as prolonged freezing or stilling or slowed “underwater” movements (see Main & Solomon, 1990, for a full description). The notion that these disorganized attachment behaviors reflect the lack of an effective attachment strategy for regaining a sense of security in the face of

stress has gained support from recent studies relating attachment disorganization to elevated cortisol secretion after exposure to brief stressors (Hertsgaard et al., 1995; Spangler & Grossmann, 1993).

As the studies in Table 10.1 indicate, disorganized infant attachment is often associated with later psychopathology. For instance, Lyons-Ruth, Alpern, and Repacholi (1993) studied 62 low-income families to examine the relation between infant attachment at 18 months and teacher ratings of child behavior problems at 5 years of age. Infant disorganization was the strongest single predictor of deviant levels of hostile behavior toward peers in the classroom, with 71% of hostile preschoolers classified as disorganized in their infant attachment relationships. Maternal psychosocial problems independently predicted hostile aggression in preschool and combined additively with infant attachment security. In a follow-up study when the children were age 7,

83% of children identified by teachers as highly externalizing were both disorganized in infancy and below the national mean in mental development scores at 18 months, compared with 13% of nonexternalizing children (Lyons-Ruth, Easterbrooks, & Cibelli, 1997).

Further support for a relation between infant disorganization and later aggression emerged from a study that followed children into middle childhood. Munson and colleagues (Munson, McMahon, & Spieker, 2001) followed a sample of 101 children who were born to teenage mothers and measured externalizing symptoms at multiple time points from preschool to third grade. Both avoidant and disorganized attachment along with maternal depressive symptoms were associated with higher levels of child externalizing problems at age 9. In another study, Shaw, Owens, Vondra, and Keenan (1996) examined disorganized attachment at 12 months, maternal personality, and child-rearing disagreements during the second year as predictors of disruptive behavior at age 5. They found that these early risk factors were as predictive of disruptive behavior at age 5 as was child aggression assessed at age 3 years.

Infant disorganized attachment has also been related to adolescent global psychopathology. In the Minnesota study, infant disorganization predicted psychopathology as assessed with the Kiddie Schedule for Affective Disorders and Schizophrenia (K-SADS) interview when participants were age 17 (Sroufe et al., 1999). Avoidant infant attachment made a further independent contribution to late adolescent psychopathology, as did measures of later experience, including parent-teen interaction at age 13 (boundary dissolution and support for teen autonomy) and problems in peer relationships.

High-Risk Samples: Internalizing and Dissociative Symptoms

Several studies have investigated infant attachment as a predictor of internalizing outcomes. Warren, Huston, Egeland, and Sroufe (1997) reported that adolescents who had been classified as resistant as infants were at increased risk for anxiety disorders (assessed in the K-SADS) at age 17. This effect was significant even after maternal anxiety and infant temperament were controlled in multiple regression analyses. In contrast, when infant anxious resistant attachment was used to predict all other types of psychopathology, no significant results emerged. Disorganized attachment was not assessed as a predictor in that study. In another study, Shaw and his colleagues (Shaw, Keenan, Vondra, Delliquadri, & Giovannelli, 1997) used a broad risk model to identify factors that increased teacher ratings of preschool internalizing prob-

lems. They found that infant attachment disorganization increased risk for internalizing, as did negative life events, parenting hassles, and child-rearing disagreements. In contrast, Lyons-Ruth et al. (1997) found that internalizing symptoms at age 7 were related to avoidance rather than disorganization.

Dissociative symptoms have also been linked to infant attachment patterns, particularly to disorganized attachment. These symptoms are thought to result from a failure to integrate different states and views of self. The failure to maintain a coherent self-organization that results in dissociative symptoms may parallel the breakdown in organized attachment strategies that results in disorganized infant behavior. Ogawa, Sroufe, Weinfield, Carlson, and Egeland (1997) investigated whether trauma, sense of self, quality of early mother-child relationship, temperament, and intelligence were related to dissociative symptoms measured at four time points across 19 years. Assessed at age 19 by the Dissociative Experiences Scale (Bernstein & Putnam, 1986) and at earlier points by teacher reports of dissociative symptoms, both the avoidant and disorganized patterns of attachment were strong predictors of dissociation at nonclinical levels. However, only disorganized attachment predicted clinical levels of dissociation. In addition, maternal emotional unavailability during the first 2 years of life was a robust predictor of clinical levels of dissociation. Surprisingly, in the most comprehensive analysis, childhood trauma predicted only teacher-reported symptoms that were concurrent with abuse in middle childhood but did not predict dissociative symptoms at age 19. Carlson (1998) further explored the antecedents and consequences of attachment disorganization to test the link between infant disorganization and later dissociative symptoms. She found that attachment disorganization was significantly correlated with environmental antecedents (e.g., maternal relationship and risk status, caregiving quality, and infant history of maltreatment), but not with infant temperament or maternal health history. In addition, infant disorganization was correlated with teens' reports of dissociative symptoms 18 years later.

In summary, the inclusion of the disorganized classification and the extension of attachment studies to high-risk samples have generally led to more consistent results linking infant attachment to subsequent psychopathology. The available studies point to several general conclusions. First, both infant avoidant and disorganized forms of insecure attachment can be understood as increasing the likelihood that a child will develop some form of psychopathology. The findings support the notion that avoidant and disorganized attachment are risk factors for a wide range of symptoms or general disorder. Although there is some support

for specific links between avoidant attachment and subsequent externalizing disorders as well as between resistant attachment and subsequent internalizing disorders, these findings are in need of replication.

Preschool Attachment and Psychopathology

During the past decade, preschool measures of attachment organization have made it possible to extend attachment research beyond infancy. Many of the initial studies have tended to focus on questions of the concurrent and predictive validity of preschool measures as well as the degree of continuity between infant and preschool attachment. Two observational systems, the MacArthur Preschool System (Cassidy et al., 1992) and the Preschool Assessment (Crittenden, 1994), rely on relatively brief separations from the caregiver to activate the attachment system. These two systems arrive at classifications of attachment organization in different ways. In one investigation of the relation between the two systems, results suggested good agreement at the level of insecurity/security and poor agreement when specific types of insecurity were compared (Solomon & George, 1999). The Attachment Q-Sort is also used to assess attachment with preschool children; raters can be either a parent or an observer.

Evidence of a link between preschool attachment and problem behavior came from a study that examined 96 children in the Strange Situation at 18 months and in Crittenden's Preschool System at 30 months (Fagot & Pears, 1996). Although there was substantial instability between the Strange Situation and Preschool classifications, much of the instability was consistent with Crittenden's predictions of developmental reorganization of the child's capacities. Concurrent observations of both parenting and child behavior at 30 months indicated that both parenting and child behaviors differed by attachment classification and predicted children's performance on achievement tests and teacher reports of problem behavior at age 7. Similarly, DeVito and Hopkins (2001) found concurrent associations between preschool attachment and disruptive behavior. Children who were classified as coercively attached (similar to resistant) scored significantly higher on the measure of disruptive behavior than either the defended (similar to avoidant) or secure children.

In a low-income sample of 223 children, Vondra and her colleagues (2001) used the Strange Situation at 12 and 18 months and Crittenden's Preschool System at 24 months. Observers coded child behavior and emotion regulation in a stressful parent-child teaching task during laboratory visits. Comparison of the Strange Situation and the Preschool Assessment classifications suggested modest stability. Preschool classifications also showed

good concurrent associations with indices of child regulation and predicted maternal reports of children's externalizing and internalizing behavior problems at age 3.5 years. The three atypical or disorganized classifications provided the best prediction of negative child outcomes.

Together, these studies lend support to a connection between preschool attachment and behavior problems. However, the cross-sectional findings leave open the possibility that coercive attachment patterns and disruptive or problem behavior are identified by similar behaviors. The two longitudinal studies that demonstrate the ability of the Preschool Assessment to account for later psychopathology provide more compelling evidence for the predictive validity of the preschool system.

The second widely used preschool assessment, the MacArthur Preschool System, has been used in both short-term longitudinal and cross-sectional studies. Seifer and his colleagues (2004) examined the attachment status of 732 children exposed in utero to cocaine, opiates, and other substances. Attachment was assessed at 18 months with the Strange Situation and 36 months with the MacArthur system. Attachment status at 18 months was associated with child temperament and caregiver-child interaction; at 36 months, attachment was associated with child temperament, child behavior problems, and caregivers' parenting self-esteem. The stability of attachment security between the two assessments was marginally above chance expectations.

Although cross-sectional studies support attachment insecurity as a risk factor for disruptive problem behaviors, only one study has examined preschool attachment risk in clinically diagnosed children. Speltz, Greenberg, and DeKlyen (1990) studied 80 clinic-referred preschool boys who were diagnosed with Oppositional Defiant Disorder (ODD) compared with a case-matched group of 80 nonproblem boys. Over half of the boys with ODD diagnoses (54%) exhibited an insecure attachment strategy during reunion, as opposed to 18% of comparison group boys. All insecure patterns were overrepresented in the clinic group. Clinic boys were also more likely than comparison boys to engage in provocative behavior when separated from their mother. The attachment classification, however, provided little concurrent prediction of problem severity or the course of the disorder in the 2 years following clinic referral.

In a follow-up to the Speltz study, Greenberg, Speltz, DeKlyen, and Jones (2001) further examined the correlates of early disruptive behavior problems, including vulnerable child characteristics, poor parenting practices, insecure attachment, and adverse family ecology. Results indicated that the combination of these factors provided relatively high sensitivity and specificity, clearly differ-

entiating referred from comparison boys. A dramatic increase in clinic status occurred when three or more factors were present, and specific combinations of factors were differentially predictive of conduct problems. However, no correlates were found to be either necessary or sufficient for clinic status.

School-Age Attachment and Psychopathology

Measurement of attachment organization in the school-age period has included both laboratory-based reunion procedures (Cassidy, 1988; Main & Cassidy, 1988) and representational measures based on narrative and story completion (Verschueren & Marcoen, 1999). The Main and Cassidy reunion procedure provides insights into how infant disorganization may be transformed during the school-age period. In addition to classifying the major attachment strategies of secure, avoidant, and ambivalent, the new system also identified several atypical patterns: controlling-punitive, controlling-caregiving, and behaviorally disorganized or insecure-other (Cassidy et al., 1992; see also Main & Cassidy, 1988). By 6 years of age, the majority of children who had been classified as disorganized infants shifted their attachment behavior into a controlling role-reversed pattern (Main & Cassidy, 1988; Wartner, Grossmann, Fremmer-Bombik, & Suess, 1994). Main and Cassidy viewed the strategy shift as an attempt by the child to resolve the paradox presented by a frightened/frightening caregiver.

Cross-sectional studies have generally identified early childhood attachment insecurity as a risk factor for aggressive or problem behaviors. Cohn (1990) found that insecurely attached first-grade boys were less well liked by peers and teachers and were perceived as more aggressive and as having more behavior problems than were their secure counterparts. Easterbrooks, Davidson, and Chazan (1993) examined the school-age attachment classifications and found that both environmental risk and insecure attachment were associated with poorer behavioral adaptation among 7-year-olds. In a larger and more representative sample of children between the ages of 7 and 9, Graham and Easterbrooks (2000) found that both attachment security and socioeconomic risk were significantly related to children's depressive symptoms. In this sample, secure attachment buffered children at socioeconomic risk for depressive symptoms.

School-age disorganized attachment has also been identified as a risk factor for psychopathology. Solomon, George, and De Jong (1995) found that 5- to 8-year-old children classified as controlling differed from other children both in their symbolic representations and behavior problems. These children demonstrated doll play characterized by themes of

catastrophe and helplessness or by inhibition of play. Moss, Parent, Gosselin, Rousseau, and St-Laurent (1996) further explored the association between school-age disorganized/controlling status and problem behaviors and found that the disorganized and controlling children were more likely to have higher teacher ratings of problem behaviors.

In a more recent study, Moss, Cyr, and Dubois-Comtois (2004) examined the correlates of attachment in a sample of 242 children, including 37 classified as disorganized. Stressful life events were measured at ages 5 to 7, along with mother-child interactive quality, parenting stress, marital satisfaction, and teacher-reported behavior problems. All three disorganized subgroups had poorer mother-child interactive patterns and more difficult family climates than secure or insecure-organized children. Analyses of the disorganized subgroups suggested that the controlling/punitive group had higher maternal reports of child-related stress, whereas the children in the controlling/caregiving group was more likely to have experienced the loss of a close family member. In comparison with secure children, controlling/punitive children had higher externalizing scores, and controlling/caregiving children had higher internalizing scores.

An important aspect of childhood involves moving toward a more integrated model of self and others. This is likely to require that children begin to integrate or generalize from their experiences in multiple attachment relationships. Verschueren and Marcoen (1999) used a story completion measure of child-mother and child-father attachment to consider how different relationships influence children's representation of self and their behavioral manifestations of self-esteem. The predictive power of child-mother and child-father attachments differed according to the domain of child functioning. The child's view of self was better predicted by the quality of the child-mother attachment representation, and the child's anxious/withdrawn behavioral problems were better predicted by the quality of the child-father attachment representation. These findings illustrate the need to broaden the scope of attachment assessment to include secondary attachment figures and the role that anxious attachment to fathers may play as a risk factor for psychopathology.

Adolescent and Adult Attachment and Psychopathology

Most studies of adolescent and adult attachment organization have relied on the AAI to identify attachment organization or "states of mind" with respect to attachment (George, Kaplan, & Main, 1996; Hesse, 1999; Main & Goldwyn, 1998). The AAI classifications generally parallel

the three major classifications identified at earlier developmental periods. Subjects who value attachment and provide a coherent description of experiences with attachment figures are judged autonomous (or secure) with respect to attachment. Subjects who devalue or divert attention from attachment topics are judged dismissing (or avoidant) of attachment issue. Subjects who are passively or angrily engaged in discussing attachment are judged preoccupied (or ambivalent). The formal characteristics of participants classified as unresolved with respect to loss or trauma parallel the descriptions of disorganized behavior in infancy. Participants are classified as unresolved if they show a momentary lapse in monitoring of reasoning or discourse during the interview. This lapse is viewed as a momentary loss of an organized strategy for directing attention to interview topics and is usually assigned along with a classification for one of the three organized discourse strategies.

The AAI was initially developed to understand how caregivers' states of mind might predict infants' attachment security (Hesse, 1999). Despite a large effect size found between caregivers' states of mind and their infants' attachment organization (van IJzendoorn et al., 1995), much remains to be understood about how adults' states of mind influence caregiving quality and child attachment. In adolescent and adult studies, the concurrent validity of the AAI depends on its ability to account for observed behavior with caregivers at times when the attachment system is activated. Adolescent AAIs have shown theoretically predicted relationships with parent-teen interaction, with secure adolescents achieving more balanced assertiveness, less anger, and more support during conflict discussions (Kobak, Cole, Ferenz-Gillies, Fleming, & Gamble, 1993), as well as higher levels of autonomy and relatedness (Allen, Moore, & Kuperminc, 1997) and age-appropriate secure base behavior (J. P. Allen & Land, 1999). More recently, Roisman and his colleagues (Roisman, Padrón, Sroufe, & Egeland, 2002) found that the quality of parent-teen interactions at age 13 predicts a secure state of mind at age 19. The AAI has also demonstrated strong stability over 2-year periods in both late adolescence (Allen et al., in press) and adulthood (Crowell et al., 2002).

Studies of adolescents' AAIs and psychopathology have been limited to samples that are at slightly elevated risk by virtue of poor school performance (Marsh, McFarland, Allen, Boykin McElhaney, & Land, 2003) or increased depressive symptoms (Kobak, Sudler, & Gamble, 1991). In the Marsh study, preoccupied teens were prone to more risky or problem behaviors when their mother was coded as high on autonomy during a parent-teen problem-solving discussion. In contrast, preoccupied teens with a mother who was low in autonomy were more vulnerable to

internalizing symptoms. These findings illustrate a transactional process, with parental behavior acting as a stressor in interaction with teen's attachment organization. Kobak and colleagues also found an association between adolescents' preoccupied states of mind and depressive symptoms.

A substantial association between severe adolescent psychopathology and AAI state of mind also emerged from a 10-year longitudinal study. Allen, Hauser, and Borman-Spurrell (1996) compared 66 adults who had been psychiatrically hospitalized at age 14 to 76 adults who had not been hospitalized. When interviewed at age 25, virtually all of the previously hospitalized adolescents displayed insecure attachment organizations, in contrast to a more typical mixture of security and insecurity in the comparison group. Unresolved trauma in the AAI accounted for much of this insecurity, and insecurity in adult attachment organization at age 25 was also linked to self-reported criminal behavior and use of hard drugs in young adulthood.

A number of investigators have conducted cross-sectional studies of adult AAI status and psychopathology (see Dozier, Stovall, & Albus, 1999, for a review). In one study of 82 inpatients and 85 case-matched controls, Fonagy and colleagues (1996) found some indications that, compared with the controls, psychiatric patients were more likely to be classified as preoccupied and unresolved with respect to loss or abuse. Anxiety disorders were associated with unresolved status, and Borderline Personality Disorder (BPD) was linked to experience of the lack of resolution of severe trauma. A similar association between unresolved trauma and borderline personality emerged from a study of 24 adult female patients with BPD or Dysthymia (Patrick, Hobson, Castle, Howard, & Maughan, 1994). These studies generally suggest that insecure states of mind are associated with psychopathology, but they leave open the question of direction of effects and for the most part have not measured caregiving in the patient's family of origin or contextual risk. Nor have they included assessments of the caregiving or attachment relationships formed with their own children.

A Continuum of Personality Risk for Psychopathology

Although attachment organization has been assessed at each phase of the life span, the majority of longitudinal studies have examined the effect of infant attachment organization on pathways to subsequent disorder. Studies of childhood, adolescent, and adult attachment organization have had to address questions of the validity of attachment measures and often have been limited to cross-sectional designs. A major area for future research will involve further validation of

postinfancy attachment measures and inclusion of these measures in longitudinal designs of high-risk samples.

Despite these limitations, the studies suggest a continuum of attachment risk for psychopathology. Not surprisingly, secure attachment generally serves as a protective factor. There is also support for the two major insecure patterns of deactivating (avoidant/dismissing) and hyperactivating (resistant/preoccupied) as risk factors for psychopathology. Deactivating attachment generally has been associated with increased risk for behavior and externalizing problems in preschool and childhood; hyperactivating attachment often has been associated with increased risk for anxiety disorders and internalizing symptoms, particularly during adolescence and adulthood. Atypical attachment patterns tend to represent increased risk for psychopathology across developmental periods. Infant disorganization, childhood controlling/punitive and controlling/caregiving, and unresolved status with respect to loss or trauma in the AAI have produced the most consistent association with more severe forms of psychopathology that include dissociative symptoms, borderline personality, or psychiatric hospitalization. There is some evidence that these atypical patterns may be further differentiated between controlling/punitive versus controlling/caregiving behaviors and between lack of resolution of loss versus lack of resolution of trauma in the AAI.

CAREGIVING AND PSYCHOPATHOLOGY: A CONTINUUM OF RELATIONAL RISK

The behavior of parents, and of anyone else in a caregiving role, is complementary to attachment behavior. The roles of the caregiver are, first, to be available and responsive as and when wanted and, second, to intervene judiciously should the child or older person who is being cared for be heading for trouble. (Bowlby, 1979, p. 133)

Despite the theoretical importance that Bowlby (1973, 1979) assigned to caregiving in understanding attachment processes, and despite Ainsworth's (Ainsworth et al., 1978) pioneering studies of caregiver sensitivity during infancy, attachment researchers have devoted relatively little effort to assessing a caregiver's availability and responsiveness beyond the infancy period. Yet, in the studies that have assessed the quality of care beyond infancy, this factor often enhances predictions made by attachment or makes an independent contribution to predicting psychopathology. Bowlby's notion that available and responsive care continues to be a critical factor beyond infancy can be further developed by considering studies of (1) caregiving quality in childhood and adolescence, (2) atypical caregiv-

ing behaviors, and (3) attachment-related traumas or the breakdown in the protective function of the caregiving environment. From a theoretical perspective, these three aspects of the caregiving environment constitute a continuum of caregiving risk for psychopathology.

Insensitive Caregiving and Risk for Psychopathology

Not only did Bowlby propose that caregiver sensitivity is an antecedent of infant attachment security (and there is substantial evidence that this is the case; DeWolff & van IJzendoorn, 1997), but Bowlby's pathways model also suggests that caregiving quality continues to be a primary factor in a child's trajectory and that insensitive care can contribute not only to the child's attachment security but also to psychopathology. This point is illustrated by Belsky and Fearon's (2002a) study in which attachment security assessed at 15 months and caregiving sensitivity assessed at 24 months were used to predict a range of developmental outcomes that included problem behaviors at 36 months. A comparison of secure children who later received insensitive care with insecure children who later received sensitive care indicated that in the case of all outcomes, insecurely attached children who subsequently experienced highly sensitive mothering significantly outperformed secure children who subsequently experienced insensitive mothering. These results highlight the importance of postinfancy quality of care in shaping children's developmental trajectories.

The studies reviewed in Table 10.1 lend further support to the continued importance of the caregiving environment in influencing developmental outcomes. For instance, Shaw and Vondra (1995) found that parenting practices were a unique predictor of problem behavior at 36 months. In the longitudinal Minnesota sample, postinfancy quality of care (at 24, 36, and 42 months) was an important predictor of psychopathology. Inadequate parenting in early childhood contributed to internalizing and externalizing symptoms in middle childhood (Renken, Egeland, Marvinney, Mangelsdorf, & Sroufe, 1989), to early onset of adolescent antisocial behavior (Aguilar et al., 2000), and to dissociative symptoms in childhood and adolescence (Carlson, 1998). Preschool assessments of permissive parenting and poor parenting practices have also been linked to ODD in the preschool period (Greenberg et al., 2001).

Relatively few attachment studies have assessed caregiving quality in the middle childhood period. However, adolescent attachment researchers have found that observational measures of dysfunctional anger and of maternal autonomy during parent-teen conflict discussion may moderate the effect of attachment security on risk behav-

iors and internalizing symptoms (Kobak et al., 1991; Marsh et al., 2003). The continued importance of measuring the caregiving relationship in adolescence is also illustrated by the contribution that observations of parent-child interaction (particularly boundary dissolution) at age 13 made to accounting for global psychopathology at age 17½ (Sroufe et al., 1999).

Deviant Caregiving and Psychopathology

The measures of caregiving quality used in many attachment studies often derive from observations of largely nonclinical low-risk samples. Thus, although dysfunctional anger, insensitivity, or maternal autonomy may all increase risk for psychopathology, many children experience these forms of care and do not develop symptoms. In many respects, these nonoptimal forms of caregiving parallel the insecure attachment patterns that may create only limited risk for the development of symptoms. As attachment researchers have considered caregiving in more extreme or clinical samples, more deviant forms of caregiving have been identified.

For instance, Main and Hesse (1990) suggested that frightening (threatening, frightened, or dissociated) parental behavior explains why infants develop disorganized attachment relationships. Schuengel, Bakermans-Kranenburg, and van IJzendoorn (1999) tested this hypothesis by coding frightened or frightening maternal behavior with infants during two 2-hour home visits. These behaviors were associated with marginally higher rates of infant disorganization in the Strange Situation. Mothers' unresolved status in the AAI further differentiated infant outcomes. Secure mothers with unresolved loss displayed less frightening behavior than other mothers, and unresolved loss in secure mothers did not predict disorganized attachment of their infants. Frightening behavior predicted infant disorganized attachment irrespective of maternal security.

Lyons-Ruth, Bronfman, and Parsons (1999) expanded the range of atypical maternal behavior by developing the Atypical Maternal Behavior Instrument for Assessment and Classification (AMBIANCE). This instrument assesses a broader range of types of disrupted affective communication between mother and infant. Disrupted affective communication was indexed by the frequency of maternal, negative-intrusive, role-confused, withdrawing, disoriented, and contradictory behaviors in response to infant cues, as well as by the frightened/frightening behaviors included on the Main and Hesse (1992) coding inventory. Lyons-Ruth and her colleagues found that, as predicted, the frequency of atypical caregiving behaviors was significantly related to the infant's display of disor-

ganized attachment. These atypical maternal behaviors, which were coded in the Strange Situation assessment, demonstrated cross-situational stability in that they were significantly related to similar behaviors observed in an unstructured home observation. In addition, higher levels of atypical maternal behavior in the Strange Situation were associated with increased infant distress at home. Neither infant gender nor cumulative demographic risk were significantly related to maternal atypical behavior.

The more surprising finding, however, was that there were substantial differences in maternal behavior *within* the group of disorganized infants, with mothers of disorganized/insecure infants displaying significantly more atypical behaviors than mothers of disorganized/secure infants. In particular, mothers of disorganized/insecure infants displayed significantly higher rates of both role confusion and negative-intrusive behavior than mothers of disorganized/secure infants. In contrast, mothers of disorganized/secure infants exhibited significantly higher rates of withdrawal than mothers of disorganized/insecure infants (Lyons-Ruth et al., 1999). However, only the mothers of disorganized/insecure infants differed significantly from mothers of organized infants in their overall rates of atypical behavior. Subsequent analyses also indicated that disrupted maternal communication was related both to maternal hostile-helpless state of mind and to lack of resolution of loss or trauma in the AAI (Lyons-Ruth et al., in press).

Goldberg, Benoit, Blokland, and Madigan (2003) coded atypical maternal behavior in 197 mother-infant pairs using the AMBIANCE codes in a free-play assessment. Both maternal unresolved status in the AAI and infant disorganized attachment were systematically related to atypical maternal behavior. These relations between disorganized maternal and child attachment and disrupted communication were subsequently replicated in a sample of adolescent mothers (Madigan, Pederson, & Moran, 2003). These data provide preliminary empirical validation for the AMBIANCE and suggest that measures of deviant caregiving may be useful in better understanding children's trajectories toward psychopathology. Further assessment of atypical types of caregiving behavior at later developmental periods could make a substantial contribution to understanding risk for psychopathology.

Attachment-Related Trauma and Psychopathology

In addition to extreme deviations in the daily quality of care experienced by children, children may be exposed to another class of events that shake their confidence in their caregiver's availability and expose them to traumatic levels of

stress. These traumatic events may be added to deviant caregiving to further expand the continuum of caregiving risk for psychopathology. Attachment-related trauma results from serious threats to the individual's well-being or survival combined with the child's appraisal of loss, rejection, or abandonment by an attachment figure (Kobak et al., 2004). Because children's survival is often dependent on their parents' availability and protection, it is not uncommon for appraised threats of rejection, abandonment, and loss to be simultaneously perceived as a threat to survival. By adulthood, threats to the availability of an attachment figure do not necessarily signal threats to survival; as a result, many adult traumas may be the product of compound fear situations in which a threat to the self is combined with a perceived threat of loss or abandonment by an attachment figure. Kobak and colleagues identified four major types of attachment-related trauma: (1) attachment disruptions, (2) physical or sexual abuse by a parent, (3) loss of an attachment figure through death, and (4) attachment injuries. These types of attachment-related trauma may influence an individual's ability to maintain organized coping and could substantially increase risk for the emergence of psychopathology.

Attachment disruptions were a major topic in both Bowlby's (1951) and Ainsworth's (1962) seminal articles on the effects of maternal deprivation. Attachment disruptions can be understood as an extreme form of separation that differ from normal daily separations by being more prolonged or involving little planning or communication with the attachment figure. The way the child appraises and evaluates the disruption will be influenced both by developmental level and by experience. Infants and young children may be particularly vulnerable to negative effects of prolonged separation, as they lack the ability to form joint plans or represent the attachment figure during the absence. Older children are more capable of managing long separation from parents as long as these separations are accompanied by planning and continued communication. The attachment-related impact of a disruption is also influenced by the child's own appraisal. For instance, a child whose parents threaten to abandon or send the child away (Bowlby, 1973) may be more likely to appraise physical separation as an abandonment or rejection. Similarly, when divorce or marital separations are accompanied by high levels of conflict or disagreements about child rearing, the child will be more likely to appraise marital separations as an abandonment (Grych & Fincham, 1993).

Kobak, Little, Race, and Acosta (2001) examined the effects of attachment disruptions on psychopathology and functioning among a group of 9- to 11-year-old boys who

had been classified as severely emotionally disturbed and a matched comparison group. Disruptions were classified on a 4-point scale ranging from maintaining a continuous relationship, to complete abandonment or loss of the attachment figure. Boys who had been placed in severely emotionally disturbed classrooms had much higher rates of attachment disruptions with their biological mothers. Across the entire sample, higher levels of attachment disruptions were associated with higher teacher ratings of dissociative symptoms and higher scores for dependency on ratings of the teacher-student relationship. The most extreme forms of disruption have been investigated in the case of young children who have been institutionalized (Chisholm, Carter, Ames, & Morison, 1995; Marcovitch et al., 1997; O'Connor, Marvin, Rutter, Olrick, & Britner, 2003).

Physical or sexual assault by an attachment figure is likely to expose the victim to feeling intensely frightened and helpless. When the perpetrator of abuse is also an attachment figure the child faces an inescapable dilemma. As Main and Hesse (1990) have pointed out, abuse creates a unique attachment-related trauma in which the child's source of safety and protection simultaneously becomes a source of alarm. Abuse creates a further problem for the child insofar as it is frequently a chronic aspect of the parent-child relationship, and the child is thus faced with an ongoing trauma. Egeland, Yates, Appleyard, and van Dulmen (2002) examined the effects of early childhood maltreatment on antisocial behavior in adolescence in a longitudinal study of 140 high-risk children and their families. The alienation from supportive social relationships that followed abuse helped to explain the relation between early maltreatment and later antisocial behavior. The link with antisocial behavior was accounted for primarily by physical abuse in early childhood, not emotional neglect.

The loss of an attachment figure through death may or may not be a frightening experience (Bonanno & Kaltman, 1999). Fear is more likely if the loss is sudden, making it impossible to prepare for the absence of the attachment figure. Fear usually accompanies the threat of loss rather than actual loss. Thus, initial news of events involving perceived danger to the life of the attachment figure can produce extreme fear even if they do not necessarily result in the death of the attachment figure. Although the threat of loss is ultimately an appraisal process that is likely to differ across individuals (Bowlby, 1980), several contextual factors are likely to make the threat of loss particularly traumatic. There is evidence that violent death is more likely to produce intense fear and difficulties following the loss in comparison with losses that occur through natural causes (Zisook, Chentsova-Dutton, & Schuchter, 1998). Bowlby

(1973) emphasized that exposure to violence or suicide threats could be particularly frightening to children.

Drawing on her clinical work with distressed couples, Johnson (2002; Johnson, Makinen, & Millikin, 2001) suggested a fourth type of attachment-related trauma. She described compound fear situations in which an adult, when faced with a life-threatening situation, feels abandoned by his or her attachment figure. According to Johnson attachment injuries are “wounds arising from abandonment by a present attachment figure in a situation of urgent need.” (Johnson, 2002, p. 15). These events are traumatic in that they elicit intense fear associated with isolation and abandonment. In addition, these events fundamentally shake the adult’s confidence in the partner’s availability and responsiveness. If attachment injuries can occur in the context of adult attachment relationships, similar events may have a profound influence on parent-child attachments. If the attachment figure ignores, dismisses, or denies distressing events, the child may feel abandoned and isolated at a time of urgent need. Diamond and Stern (2003) have identified these moments as the basis of potential impasses in treatment of adolescent children and their parents.

A Continuum of Caregiving Risk for Psychopathology

The continuum of caregiving risk in many ways parallels the continuum of attachment risk. Whereas insensitive caregiving has been associated with insecure attachment, more extreme forms of deviant caregiving behavior such as frightened or frightening parenting or disrupted affective communication have been associated with disorganized attachment. Although researchers have had some success in identifying nonoptimal patterns of caregiving in parent-teen dyads that are associated with teens’ attachment insecurity in the AAI (Allen & Land, 1999), much less research is available on more deviant types of caregiving behavior at later periods of development. The codes for frightened or frightening behavior (Main & Hesse, 1992) or disrupted affective communication (Lyons-Ruth et al., 1999) need to be extended to later developmental periods.

Observations of caregiving behavior at later periods have identified several types of atypical behavior related to boundary dissolution that have been developed (Fish, Belsky, & Youngblade, 1991; Sroufe, Jacobvitz, Mangelsdorf, DeAngelo, & Ward, 1985). The form that deviant caregiving will take is likely to change with development. In infancy, atypical caregiving may be readily apparent from the parent’s unusual and contradictory affective

communication with the infant. However, in later developmental periods, the child may have developed strategies for coping with atypical parental behaviors, including extreme avoidance and disengagement, that make it more difficult to observe deviant caregiving behavior. As a result, the child’s strategies for coping with deviant care may need to be assessed as part of a continuing relational pattern or a relational diathesis for psychopathology (Lyons-Ruth & Jacobvitz, 1999).

In addition to the more microanalytic measures of caregiving provided by observational coding systems, measures of attachment-related trauma could make an important contribution to measuring the caregiving risk that may substantially increase risk for psychopathology across the life span. Children at all ages remain vulnerable to more extreme forms of attachment-related trauma. A central contribution of attachment research in infancy and early childhood has been the identification of traumatic experience in early periods of development. Work on the sequelae of early trauma needs to be supplemented by assessments of later attachment-related traumas that may seriously deflect children toward psychopathology.

CONTEXTUAL STRESSORS AND SUPPORTS: A CONTINUUM OF CONTEXTUAL RISK

The surrounding family or *caregiving context* represents a more distal component of the caregiving environment than quality of care. A variety of factors have been considered possible contextual influences on child attachment and psychopathology. These factors fall into three broad categories: (1) stress and poverty (including educational attainment, income-to-needs ratio, minority status, and stressful life events), (2) personality and psychological health of the caregiver (see Belsky, 1999, for a review), and (3) marital or adult attachment relationships (Owen & Cox, 1997).

The caregiver’s state of mind assessed in the AAI has introduced an additional element into consideration of the caregiving environment and its effect on developmental pathways leading to psychopathology. By providing a measure of the caregiver’s attachment organization, new questions can be considered about how the caregiver’s attachment may mediate or moderate the effects of caregiving quality and caregiving context on the child. A secure or a free-to-evaluate state of mind in the AAI has been linked to infant attachment organization, and it may also play an important role in enhancing supportive family relationships and helping the parent to cope with contextual stressors.

Poverty, Caregivers' Psychological Health, and Cumulative Risk

The studies in Table 10.1 linking attachment insecurity to symptom outcomes have extensively relied on low-income samples. Many of these contextual risk factors are related to poverty and include financial strain, residential mobility, neighborhood risk, teen parenting, single-parent status, and increased levels of negative life events. Factors associated with poverty may increase risk for psychopathology in several ways. First, many of the factors associated with poverty, such as financial strain, neighborhood violence, unemployment, and residential mobility, are likely to increase both caregiver's and child's stress exposure. When combined with limited educational and employment opportunities, stress may become both chronic and cumulative and reduce the caregiver's and child's capacity to successfully cope. Second, additional factors related to caregivers' personality and mental health status, such as caregiver depression, substance abuse, and antisocial behavior, may further reduce the caregiver's ability to manage the stressors associated with poverty.

When poverty cofactors and caregiver adjustment difficulties are combined into cumulative risk indices, these factors often account for substantial variance in psychopathology outcomes in both children and adults (Aguilar et al., 2000; Shaw et al., 1996). These stressors operate cumulatively in the development of antisocial behavior and are often associated with low SES (Ackerman, Izard, Schoff, Youngstrom, & Kogos, 1999; Bolger, Patterson, Thompson, & Kupersmidt 1995). The cumulative risk model provides a way of identifying a continuum of risk as the number of risk factors increases for an individual or family.

Contextual risk factors and cumulative risk models have formed a critical third level of analysis in most of the studies of attachment and psychopathology. In many of these studies, contextual risk factors produce main effects on symptoms that are independent of attachment or caregiving risk. Contextual risk has also provided a context for identifying more extreme disorders in both attachment and caregiving. Risk factors have generally increased the likelihood of children moving from organized attachment strategies to less coherent strategies (Egeland & Sroufe, 1981; Lyons-Ruth et al., 1991; Spieker & Booth, 1988; Vaughn et al., 1979). Risk factors have also played an important role in accounting for instability of attachment classification from 12 to 18 months (Barnett et al., 1999; Egeland & Erickson, 1987; Egeland & Farber, 1984; Thompson et al., 1982; Vondra et al., 1999).

Although cumulative risk has formed an important background for investigations of attachment and psychopathology, a central question concerns whether attachment theory can contribute to conceptualizing how contextual risk operates to produce child psychopathology. That is, to what extent can an attachment model differentiate the types of contextual risk factors that are most likely to influence attachment organization, caregiving quality, and symptom outcomes? Attachment theory can identify several types of attachment-related contextual risks. These include insecure adult attachment relationships, attachment-related family-of-origin experiences, representations of attachment that influence caregiver personality, and parenting stressors.

Insecure or Violent Adult Attachment Relationships

The relationships that the caregiver has with other adults may serve either to protect the caregiver from contextual stressors or increase the caregiver's vulnerability. Insecure adult attachments may create risk to children in a number of ways. Most obviously, if a caregiver is insecure in an adult relationship, that anxiety may preoccupy him or her and reduce the quality of available and responsive care to the child. The insecurity of adult relationships may conform to a general continuum, ranging from insecure but stable relationships to violent relationships. A substantial literature suggests that exposure to partner violence has a negative impact on children's development (see Grych & Fincham, 1990, for review). Correlational data indicate that exposure to interparental violence in childhood is associated with prospective indices of child behavior problems (Grych, Jouriles, Swank, McDonald, & Norwood, 2000). Several studies have found that exposure to partner violence has a particularly strong impact on infants and preschoolers (Fantuzzo, Boruch, Beriama, & Atkins, 1997).

Family of Origin and Caregiver States of Mind

The resources that a caregiver brings to managing contextual stressors may vary both with the quality of support available in adult relationships and with the internal personality resources that the caregiver uses to cope. The AAI has made a major contribution to assessing attachment-related aspects of the caregiver's personality. By assessing attachment-related aspects of the caregiver's personality, the AAI makes it possible to consider how adult attachment security may moderate the effects of cumulative stress on the quality of care and child psychopathology. Main and

Goldwyn (1998) have identified two forms of secure individuals with the AAI: those who coherently depict a continuous history of secure relationships with parents (continuous secure) and those who probably had not been securely attached in childhood yet who currently value attachment and provide a coherent description of past experiences (earned secure). Lichtenstein, Belsky, and Crnic (1998) examined whether earned secure individuals would be similar to continuous secure individuals in their ability to provide available and responsive care to their children under conditions of high stress. Results indicated that insecure states of mind were associated with poor-quality parenting, whereas the earned and continuous secures both provided higher quality of parenting in conditions of high stress. Additional links between unresolved or hostile-helpless states of mind and atypical caregiving behavior were reviewed earlier in relation to caregiving risk.

Insecure states of mind in the AAI may also increase contextual risk if they contribute to the caregiver's risk for psychopathology and adjustment difficulties. Although the studies of the AAI and psychopathology are almost entirely limited to cross-sectional designs (see Dozier et al., 1999, for a review), they do suggest that adult insecurity is associated with increased parental psychopathology.

Parenting Stressors and Caregiver Burden

Attachment theory may also contribute to understanding caregiving context by directing attention to the aspects of the parent-child relationship that create stress for the caregiver. These stresses may include conflictual parent-child relationships, as well as the burden imposed by having to manage a child who is having difficulties with successfully adapting in school and peer contexts. Another aspect of parenting stress is related to the number of children. It is likely that the caregiver's level of stress may increase substantially with the number of children in the family, particularly when children are experiencing major adjustment difficulties or psychopathology. These types of stressors may substantially reduce available and responsive care and may in some cases increase the risk for hostile parenting or abuse.

A Continuum of Contextual Risk for Psychopathology

Caregiving context may be broadly conceived as both the distal factors that influence daily family life, the more proximal interpersonal processes that influence the caregiver-child relationship, and the caregiver's personality or internal

resources for coping with stress and maintaining close relationship. Contextual stressors may be roughly categorized into attachment- and non-attachment-related categories. Non-attachment-related stressors tend to include the more distal poverty cofactors, including financial hardship, residential instability, low level of caregiver education, teen parenthood, and neighborhood-related risk. These might be considered a more distal set of variables that create a context for caregiving and attachment. More proximal attachment-related stressors are created by insecurity or threats to the availability of the caregiver's attachment figures. These stressors often involve conflict and lack of security in the caregiver's close relationships with his or her family of origin, with other adults, and with children. These attachment-related stressors include insecure, conflicted, or violent adult attachment relationships, insecure or unresolved caregiver states of mind with respect to family of origin, and high levels of parental burden created by child difficulties and large numbers of children. In each of these categories, a continuum of risk can be identified. Studies of contextual risk might benefit by creating separate continua for attachment- and non-attachment-related contextual risk in calculating cumulative risk indices.

Contextual stressors can directly and indirectly transact with children's developmental pathways. First, distal stressors such as poverty that operate at the contextual level may *directly* influence the child's personality and adaptation by limiting educational opportunities in the home and school, creating more neighborhood difficulties, and increasing the likelihood of peer difficulties. Second, contextual level stressors may influence the child *indirectly* by their effect on the child's caregiver. If the caregiver can successfully manage the stresses associated with poverty in a way that maintains the caregiver's availability and responsiveness to the child, the child may be protected from the negative effects of contextual stressors. Risk to the child is increased when more distal sources of contextual risk are compounded with the caregiver's interpersonal stressors.

MODELING TRANSACTIONAL PROCESSES IN DEVELOPMENTAL PATHWAYS LEADING TO PSYCHOPATHOLOGY

An attachment model of developmental pathways posits ongoing bidirectional transactions among personality, caregiving, and contextual risk. Risk at one level transacts with risk at other levels. As risk becomes more extreme at any one level, the probability of psychopathology increases. Risk in one period of development may increase the proba-

bility of poor adaptation at a later period. A comprehensive theoretical model of contextual, caregiving, and attachment risk poses several major challenges for researchers. First, an adequate test of the model requires assessment at each level of analysis across developmental periods. Second, the ongoing transactions among contextual, caregiving, and attachment levels across developmental periods are complex and difficult to model. During the past 20 years, research on attachment and psychopathology has evolved to address increasingly sophisticated models of pathways leading to psychopathology. Beginning with relatively simplistic main effects models of infant attachment insecurity as a predictor of psychopathology, attachment researchers have moved to more complex multilevel models of risk that come closer to capturing the complexity of Bowlby's theory. Much of this evolution was fostered by a generation of studies of high-risk samples and an understanding of contextual variables that influence both caregiving and attachment. The development of the AAI has also offered new opportunities to consider how adult attachment organization moderates the effects of contextual risk on caregiving quality and child outcomes.

Main Effects Models

The relation between attachment insecurity and psychopathology remains a central issue in developmental pathways models. However, this view of attachment as a main effect for psychopathology has changed. A newer view of attachment insecurity focuses on the conditions in which attachment insecurity is a risk factor for psychopathology. Our review of the literature suggests that conditions of caregiving or contextual risk greatly increase the effect of attachment insecurity as a risk factor for psychopathology.

Atypical attachment and caregiving behaviors may produce reliable main effects for psychopathology. These more extreme forms of attachment disorder include disorganized attachment behaviors in infancy, child controlling attachment behaviors in childhood, and adolescent and adult unresolved states of mind with respect to loss and trauma. These new classifications introduce a range of more severe forms of attachment insecurity that may produce larger effects as simple predictors or correlates of psychopathology (see Figure 10.1). In addition, the development of reliable and valid measures of atypical attachment organization for older children and adults may offer more stable and reliable measures of attachment-related deviations at older ages. Such deviations are likely to be more stable and more similar to personality traits and potentially more predictive of psychopathology. The many cross-

Figure 10.1 Main effects model of attachment and caregiving risk for psychopathology.

sectional studies of adult AAIs and psychopathology (Dozier et al., 1999) suggest that this measure may have more potential for discovering simple main effects. However, once again, many of these cross-sectional findings were discovered in clinical or high-risk samples, leaving open the question of direction of effects.

Cumulative Risk Models

The study of high-risk samples also helped attachment researchers to add contextual and caregiving risk to the earlier studies that focused exclusively on attachment risk. In assessing contextual risk, attachment researchers could draw from other risk studies that had primarily focused on contextual variables. These studies suggested that single risk factors rarely produced significant effects on symptom outcomes. However, the accumulation of multiple risk factors produced much more consistent negative effects on children's development outcomes (Liaw & Brooks-Gunn, 1994; Rutter, 1979; Sameroff, Seifer, Baldwin, & Baldwin, 1993). Cumulative risk indices have also been assessed by adding the various risk factors associated with low SES status, such as low income, residential instability, neighborhood risk, and low level of caregiver education (Ackerman et al., 1999). Using cumulative risk as a general index of contextual stressors provides a way of measuring risk at the contextual level. A number of attachment researchers have also developed measures of caregiving risk (Lyons-Ruth et al., 1993; Seifer et al., 2004; Shaw & Vondra, 1995). The Minnesota longitudinal study increased the reliability of measures of the caregiving environment by aggregating ratings of caregiving quality across multiple observations of caregivers and children in the first 4 years of life (Weinfield et al., 1999).

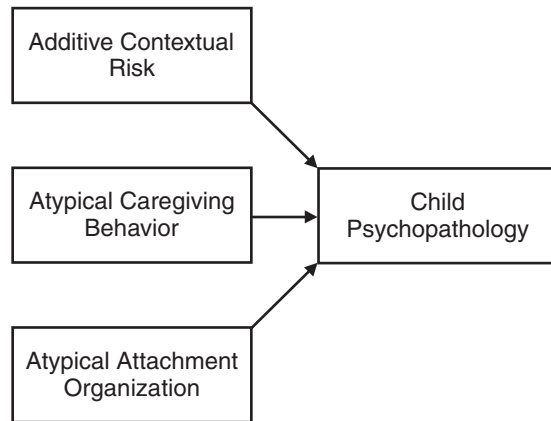

Figure 10.2 Additive model of contextual, caregiving, and attachment risk for psychopathology.

By measuring risk at multiple levels of analysis, more comprehensive models of psychopathology can be tested. Additive models were an initial step in this direction by including contextual, caregiving, and attachment risk as multiple independent predictors of later psychopathology (see Figure 10.2). Studies that adopted this approach often found that each of the levels of risk added unique variance to symptom outcomes (Kobak et al., 1991; Lyons-Ruth et al., 1993, 1997). For instance, Shaw and Vondra (1995) found that both parenting conflicts and caregivers' exposure to stressful events added to infant disorganized attachment in predicting children's internalizing problems at 36 months. Other tests of the additive model have found that the prediction of psychopathology is enhanced when contextual and caregiver risk are added to infant attachment measures (Carlson, 1998; Sroufe et al., 1999).

Mediational Models

Assessing the multiple levels of contextual, caregiving, and attachment risk also makes it possible for attachment researchers to consider how the effects of risk at one level of analysis might be mediated through its effect on risk at another level of analysis. There are several possible mediational models of attachment processes (see Figure 10.3). The most widely tested model views quality of care as a mediator between the caregiver's state of mind in the AAI and the infant's attachment organization (van IJzendoorn, 1995). Although there is some evidence that caregiver sensitivity mediates some but not all of the relation between the caregiver's attachment state of mind and infant attachment, the transmission gap suggests that there may be other processes linking caregiver state of mind to infant attach-

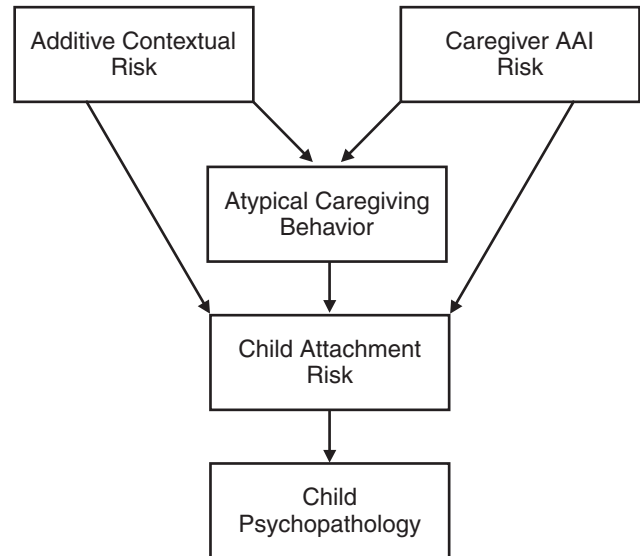

Figure 10.3 Mediational model of attachment-related risk for psychopathology.

ment. For instance, if an insecure caregiver state of mind increases risk for contextual stressors, such as depressive symptoms or relationship instability, contextual stressors might mediate some of the association between the caregiver's state of mind and the child's attachment security.

There are a number of other mediation models relevant to attachment. These include (1) the child's attachment risk mediating the relation between caregiving risk and psychopathology, (2) the child's attachment risk mediating the link between contextual risk and psychopathology, and (3) the parent's AAI risk mediating between contextual risk and psychopathology. For instance, investigators have found that negative and coercive parenting elicits coercive cycles of parent-child interaction that are often associated with child externalizing problems (Patterson, DeBaryshe, & Ramsey, 1989). Attachment may be relevant to these processes insofar as parent-child coercive cycles increase attachment insecurity or disorganization and subsequent externalizing behavior. Attachment risk may also mediate between contextual risk and psychopathology. For instance, cumulative contextual stressors have often produced main effects for externalizing problems (Conger et al., 2002). An attachment model would test the extent to which attachment risk mediated this relationship.

To date, there have been relatively few tests of mediational models of attachment processes. However, developmental psychopathology studies have documented significant relations between different levels of analysis (e.g., the link between contextual and caregiving risk). For

example, a number of studies suggest that contextual risk can increase caregiving risk to the child by reducing the quality of care available to the child. Stress for the parent reduces his or her availability to the child and increases the likelihood of harsh or abusive parenting (McLoyd, 1990). Pianta, Egeland, and Sroufe (1990) examined maternal sensitivity from 6 and 24 months to 42 months. Decreased maternal sensitivity was predicted by stressful environmental and child characteristics for both boys and girls. If maternal insensitivity increases the child's risk for psychopathology, caregiving risk could be tested as a possible mediator.

A growing number of attachment studies indicate that contextual risk can increase the child's risk for an insecure or disorganized attachment. For example, contextual factors such as poor family support, chronic drug use, foster care placement, family violence, conflictual relationships with parents, parental depression, paranoia, antisocial behavior, and sexual exploitation increase the child's risk for insecure attachment (Das Eiden, Peterson, & Coleman, 1999; Lyons-Ruth, Lyubchik, Wolfe, & Bronfman, 2002; Seifer & Schiller, 1995; van IJzendoorn, 1995; van IJzendoorn & Bakermans-Kranenburg, 1996). Finally, an extensive literature suggests that caregiving insensitivity increases risk for insecure attachment (i.e., insecurity; see Belsky, 1999, for reviews) and that frightened, frightening, or atypical maternal behavior accounts for significant variance in disorganized attachment (Goldberg et al., 2003; Lyons-Ruth et al., 1999; Madigan et al., in press; Schuengel et al., 1999).

Although there is empirical support for parts of each of the mediation models, showing links between one level of analysis and the next does not provide a full test of mediation. These models would need to include symptom outcomes and show that the effect of one level of analysis on symptom outcomes is fully mediated through a second level of analysis.

Diathesis Stress Models

Attachment theory suggests that secure attachment organization promotes resilient coping with stress, and insecure attachment organization generally results in less adaptive coping. The notion that insecure attachment is most likely to increase risk for psychopathology under high-stress conditions is consistent with a diathesis stress model of attachment and psychopathology (see Figure 10.4). At a theoretical level, it has been suggested that symptoms are most likely to emerge when organized coping strategies breakdown (Kobak, Ferenz-Gillies, Everhart, & Seabrook, 1994;

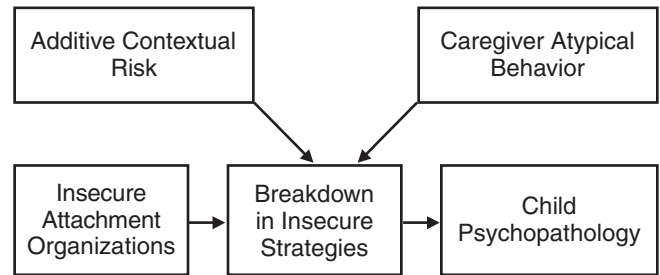

Figure 10.4 Diathesis stress model of attachment-related risk for psychopathology.

Kobak & Shaver, 1987). This breakdown in organized coping is most likely under high or chronic stress conditions. By considering a continuum of contextual risk (i.e., varying levels of stress or “allostatic load”; McEwen, 1998), we can test the notion that psychopathology is most likely when individuals with insecure attachment face high levels of stress.

Not only may the child's insecure attachment organization serve as a diathesis for psychopathology, but theoretically, the caregiver's insecure state of mind in the AAI could also serve as a diathesis for caregiver psychopathology or breakdowns in the caregiving system. By providing a measure of adult attachment security, the AAI makes it possible to test the notion that insecure attachment is a diathesis for psychopathology that is most evident under conditions of stress in both children and their caregivers. By considering both child and caregiver attachment insecurity as a diathesis for psychopathology, several types of diathesis stress models can be tested. Examples of these include (1) contextual/interpersonal stressors x child attachment organization = child symptoms, (2) contextual/interpersonal stressors x caregiver states of mind = caregiver psychopathology, and (3) parent-child conflict x child attachment organization = child psychopathology.

A critical question for a diathesis stress model of attachment and psychopathology is identifying and measuring the sources of stress encountered by the child and caregiver. Belsky and Fearon (2002b) drew on cumulative risk models to index stressors to which children were exposed in the NICHD study. They used a cumulative risk model to measure the social context of the 946 children from 1 to 36 months. Attachment security at 15 months was tested as a moderator of the association between contextual risk and problem behaviors at age 3 years. The effect of attachment insecurity varied as a function of contextual risk. Insecure-avoidant infants who were exposed to high levels of contextual risk proved most vulnerable to developing problem behaviors. These findings

highlight the importance of moving away from simple main effects models linking attachment insecurity to psychopathology. In this large sample, avoidant attachment increased risk for problem behaviors only when infants experienced high levels of cumulative risk.

Another way to evaluate diathesis stress models is to use laboratory tasks that allow observation of behavior under varying levels of stress or challenge (Kobak & Duemmler, 1994). Marsh and colleagues (2003) tested a diathesis stress model of attachment and psychopathology based on a conflict discussion between mothers and teens. They found that teens' preoccupied attachment was associated with differential symptom outcomes depending on the degree to which mothers asserted autonomous opinions during the interaction. Low displays of maternal autonomy resulted in preoccupied teens having more internalizing symptoms, and high displays resulted in preoccupied teens having more risk behaviors. The nature of the stresses that teens with high- and low-autonomous mothers experience needs further investigation, but presumably extremes in maternal behavior increase the child's stress in the parent-teen conflict discussion. These stresses, when combined with an insecure attachment strategy, result in increased psychopathology.

Early Experience Models

A central question for a developmental pathways model is the extent to which early experiences with attachment security, caregiving quality, and contextual stressors continue to exert an influence on the child's adaptation beyond the child's current attachment security and caregiving environment. This question becomes important in light of the discontinuity demonstrated in developmental pathways. Longitudinal studies have demonstrated that children's adaptation can dramatically change from infancy and early childhood to later developmental periods (Roisman et al., 2002; Sroufe, Egeland, & Kreutzer, 1990). Whereas some children with insecure relationship histories move toward more adaptive functioning in childhood and adolescence, other children with secure histories may encounter substantial adversity that results in problem behavior. The early experience hypothesis suggests that early relationship history should continue to account for significant variance in later adaptation beyond that accounted for by contemporaneous assessments of the child's environment (see Figure 10.5). Although there are a number of longitudinal studies that include infant attachment, relatively few studies control for concurrent functioning when using early experience to account for later outcomes.

Figure 10.5 Early experience model of attachment-related risk for psychopathology.

Tests of the early experience hypothesis require high standards of measurement across developmental periods. The Minnesota study has established a standard in this respect; as a result, the initial tests of the early experience hypothesis come primarily from this study. Sroufe et al. (1990) divided 190 high-risk children into two groups. One group showed positive adaptation in the infant/toddler period followed by poor preschool adaptation, and the other group showed consistently poor adaptation in both the early and later periods. The two groups were then compared in elementary school. Children who showed positive adaptation in the infant/toddler period showed greater rebound in the elementary school years, despite poor functioning in the preschool period.

Yates, Dodds, Sroufe, and Egeland (2003) provided a further test of the early experience hypothesis with respect to how caregiving context may influence child psychopathology. Partner violence toward mothers was measured from multiple interviews when the children were in the preschool period (age 18 to 64 months) and again during the early elementary school years. Later exposure to partner violence was entered to account for later teen psychopathology at age 16. In addition, other variables, including abuse history and stressful life events, were controlled. Yet, even with later exposure to partner violence controlled, preschool partner violence accounted for externalizing adolescent symptoms in the case of boys and internalizing adolescent symptoms in the case of girls.

SUMMARY AND FUTURE DIRECTIONS

Over the past 2 decades, there have been substantial advances in research examining attachment and psychopathology. The early attachment and psychopathology studies often tested relatively simple models of infant attachment insecurity predicting psychopathology in low-risk samples. During the past 15 years, the extension of attachment research to high-risk samples has led to several important advances. First, investigators have tended to view attachment-related risk in the context of other risk factors. This has led to more powerful models of the development of psychopathology and a better understanding of the role that attachment plays in the emergence of symptoms. Second, the study of high-risk samples has led to an expansion of classifications to include atypical attachment behaviors that may be more closely linked with psychopathology. Furthermore, more recent studies have been based on larger sample sizes that allow investigators to test more complex models of developmental pathways, including early experience and diathesis-stress models.

Each of these advances has moved attachment research closer to testing the transactions between attachment and caregiving that formed the core of Bowlby's developmental pathways model. Yet, there are several major challenges to further advances in the field. These include developing measures of attachment organization across the life span, assessing not only caregiving quality but also the role that adult internal models of attachment play in the caregiver's personality and ability to manage stress, and examining how more distal contextual risk factors may influence more proximal stress exposure for both the child and the caregiver. Each of these challenges suggests important directions for future research.

Measuring Attachment Organization

Attachment organization is a complex construct that is difficult to measure. It not only consists of core expectations about the availability and responsiveness of attachment figures, but also comes to form the basis for expectations about the self, including a sense of self-worth and self-efficacy. In addition, these core expectations, or internal working models, are thought to guide strategies for regulating attachment behavior, particularly in contexts involving distress or challenge. Ainsworth's Strange Situation has become the gold standard for measuring attachment organization in infancy and as a result has been extensively used in studies of development and psychopathology.

Two approaches have been taken to validating attachment measures in the preschool and childhood period. One approach is to assume continuity between infant attachment and subsequent measures of attachment. This approach assumes that later measures should correlate with the infant measures. The relative lack of stability in attachment organization even between 12 and 18 months in the Strange Situation makes this a questionable approach. As we have seen, Bowlby viewed early attachment organization as sensitive to the caregiving environment and thus as subject to change during this period. A second approach is to expect that an attachment organization be validated against measures of attachment behavior in the natural environment (Weinfield et al., 1999). Although home observations are an invaluable source of information about caregiver sensitivity in infancy, the opportunity to observe attachment behavior in the natural environment decreases with age as the child's growing capacities make the readily observable instances of reliance on the caregiver much less frequent.

Attachment research could benefit from more traditional approaches to construct validation. These approaches begin with the use of strategies to reduce measurement error. The use of single assessments of attachment security has inherent limits. Multiple methods and multiple measures are one of the most effective ways of reducing measurement error. Even the Strange Situation assessment in infancy has been shown to have systematic sources of error (e.g., David & Lyons-Ruth, 2005) and can benefit from multiple assessments. In the Minnesota study, measurement of attachment security was substantially improved by aggregating Strange Situation assessments at 12 and 18 months (Weinfield et al., 1999). In preschool and childhood, measures of attachment organization could make much more extensive use of multiple measures. Models of self and other, as well as the assessment of attachment strategies, need to be better operationalized. For example, the notion of self/other expectancies could be rated by observing behavior in situations designed to activate the attachment system, and as the child grows older, by other methods, including self-report and narrative methods such as story completion measures.

The AAI has proved useful in assessing teens' attachment organization, and the three organized attachment categories have been validated with concurrent measures of the observed quality of communication during parent-teen conflict discussions (Allen & Land, 1999; Kobak et al., 1993). The unresolved category remains to be similarly validated in this age range. An important point in all these studies is that measurement error can be reduced both by repeated measures and by the use of multiple

methods. In sum, future research on attachment organization needs to move away from single measures of the attachment construct.

As attachment researchers develop and validate measures of attachment organization, more description is needed of atypical attachment patterns and behaviors. The identification of controlling attachment strategies in childhood (Main & Cassidy, 1988) and hostile-helpless states of mind in adulthood (Lyons-Ruth et al., *in press*) demonstrates the value of extending description to capture aspects of attachment that deviate from more typical forms of insecurity. Moreover, the factors that influence attachment organization at later periods of development need further consideration. Not only are multiple caregivers likely to have an influence and contribute to a child's attachment organization, but experiences with peers become increasingly important, particularly with the development of adolescent romantic relationships (Furman, Simon, Shaffer, & Bouchev, 2002).

Understanding the Caregiver

Attachment researchers have often spent more time studying children and their attachment organization than they have spent studying the children's caregivers. As a result, the caregiving side of the attachment relationship is less well understood. The lack of research on caregiving is surprising in light of the degree of importance that the caregiving environment plays in Bowlby's pathways model. Caregiving behavior is organized by a caregiving behavioral system whose biological function is to provide protection and support for the developing child (George & Solomon, 1999). The caregiving system normally engages the parent in ongoing monitoring of the child's needs and accounts for the parent's investment in the child's success in ultimately reproducing and caring for the next generation. The caregiving system promotes a sensitivity to the child's signals that complements the child's need to experience the parent as available and responsive. A caregiver's success in achieving the goals of protection and nurturance of the child can be a source of pride, and child difficulties that signal a failure to achieve these goals can be a source of guilt and lead to a sense of failure.

Because the infant's sense of security depends not on adult-perceived physical safety but on the child's experience of caregiver responsiveness, success in caregiving depends on the caregiver's ability to attend to, interpret, and respond to the child's needs and signals (Ainsworth et al., 1978). Ainsworth's measures of sensitivity provided a basis for assessing caregiving quality in infancy. However, devel-

opmental changes in the child require new measures of caregiving quality at later developmental periods. Laboratory interaction paradigms may be particularly useful in assessing caregiving quality in later developmental periods (see Allen & Land, 1999; Crowell, Treboux, Gao, et al., 2002; Kobak et al., 1993). Observational paradigms have been widely used by researchers using descriptive dimensions of caregiving quality, such as support validation, negative comments, and support for autonomy, and many of these dimensions may be useful to attachment researchers. Future studies need to consider whether there are aspects of optimal parenting that are clearly more important to a child's attachment security.

A critical area for future research centers on the factors that facilitate or hinder the caregiver's ability to provide available and responsive care to the child. Two major types of factors are relevant to caregiving. On the one hand, there are the contextual stressors and supports that have been identified in the pathways model. On the other hand, there are individual differences in the internal resources that caregivers bring to the parent-child relationship. The development of the AAI has provided a valuable tool for better understanding individual differences in caregivers' internal resources and coping capacities. Further, the links that have been identified between insecure states of mind and adult psychopathology (Dozier et al., 1999) suggest that states of mind may have profound influence on adult functioning and potentially reduce the caregiver's availability and responsiveness to the child.

Caregivers' states of mind in the AAI may also have an important influence on how the caregiver manages the contextual stressors and supports that shape children's developmental trajectories. For instance, a secure state of mind may promote the development of supportive adult relationships and support more effective coping with the stressors associated with poverty. To the extent that the caregiver develops supportive adult relationships and effectively manages stressors, he or she is likely to maintain the capacity to remain available to the child. As a result, the child's risk for experiencing deviant care and the associated risk for psychopathology is substantially reduced. Alternatively, a caregiver whose state of mind is characterized by lack of resolution of trauma may be at increased risk for insecure adult attachments that are a source of stress rather than support. Further, when faced with cumulative levels of high stress, this caregiver's strategies may be vulnerable to breaking down and to the emergence of symptoms. Overwhelmed by contextual stressors and the symptoms of his or her own psychopathology, the caregiver is likely to have much more difficulty maintaining available and responsive

care to the child. Further, these stressors may lead to an abdication of the caregiving role or basic violations of caregiving boundaries (Fish et al., 1991; Sroufe, Jacobvitz, et al., 1985), which may substantially increase the child's risk for atypical attachment and psychopathology. The transactions among caregiver states of mind, contextual supports and stressors, and caregiving quality are a promising but largely unexplored area for attachment research (Kobak & Mandelbaum, 2003).

Identifying and Measuring Stressors in the Caregiving Environment

Both attachment research and studies examining risk have consistently found that accumulating risk factors substantially elevate children's risk for psychopathology. However, the mechanisms that link cumulative risk to caregiving and attachment are poorly understood. We have suggested that stress models represent an important way of linking contextual risk to caregiving and attachment. From the standpoint of attachment theory, stress normally activates the attachment system, and seeking proximity and support from a caregiver is a primary mechanism for coping with stress. Further, the experience of high levels of stress may hinder the caregiver's capacity to provide available and responsive care. Thus, we have proposed a diathesis-stress model of attachment and psychopathology. This model posits that insecure and atypical attachment strategies are particularly vulnerable to breaking down under conditions of high stress and leaves the individual at increased risk for maladaptive responses and symptomatic behavior under conditions of high stress.

Although diathesis-stress models are a theoretically compelling approach to understanding the links among contextual risk, attachment, and psychopathology, the degree to which contextual risk factors are experienced as stressful by caregivers and children is in need of further investigation. At least three levels of contextual stress may be distinguished: (1) distal factors that influence the family environment, such as poverty and poverty cofactors (e.g., residential mobility, low educational attainment); (2) more proximal factors, such as caregiver personality and psychopathology; and (3) relationship processes. Relational factors have two aspects. Well-functioning relationships can serve as a stress buffer and support; alternatively, conflicted relationships can serve as a major source of stress exposure.

In assessing relational stressors it is important to distinguish caregiver stressors from child stressors. If the caregiver has the personality resources to cope with stress,

caregiving quality may be maintained and the child may be protected from stressors. The effect of stress on the attachment relationship may also be bidirectional. When the child experiences high levels of stress in the neighborhood, school, or peer contexts, these may impact the child and create challenges and stress for the caregiver. By categorizing distal and relational stressors, new questions can be addressed that might increase the specificity of cumulative risk models. Some stressors may have more impact on the child than others, and the degree to which caregiving is affected by stress could vary substantially.

Finally, it is important to use multiple methods for assessing stress. Whereas many of the early studies relied on caregiver reports of major disruptive events, later studies moved toward smaller and more frequently occurring sources of stress. Stress may be measured at multiple levels, ranging from individual child and caregiver physiology, to daily interpersonal stressors, to environmental stressors associated with poverty, to major disruptive life events such as loss and trauma.

Testing Models of Transactional Processes
